Noise and adaptation should be set within some appropriate range so that correlations between successive perceptual durations are weak or absent, consistent with the experimental data. Indeed, if adaptation is too strong, during a long phase of dominance, the active population recruits a lot of adaptation, and when this population becomes suppressed, a long phase of recovery will be necessary before the next switch can occur. In the double-well case, if the ball jumps from one well after a long residence time, it falls into the other, now very deep, well; the barrier between wells is very high and the ball must wait a long time before it can switch back. These relations between successive durations lead to strong positive correlations.

Finally, for mutual inhibition models (irrespective of being noise or adaptation driven), one can distinguish two mechanisms for which transitions may take place: escape and release. For the release mechanism, the dominant population weakens (due to the slow self-adaptation) allowing the suppressed one to take over. However, for the escape mechanism, the suppressed population takes over after recovering from self-adaptation, suppressing the active population. In Shpiro, Curtu, Rinzel, and Rubin (2007), the authors identified these two mechanisms in different parameter regions for the models in Laing and Chow (2002) and Wilson (2003) as well as other models based on mutual inhibition. They found

that these models only satisfy Levelt's IV proposition when set in an escape mechanism. In Seely and Chow (2011), various biophysically plausible modifications to mutual inhibition models are proposed to resolve this issue.

Other Models of Perceptual Bistability

Centralized Mechanism of Perceptual Decision

Pettigrew and colleagues (Carter and Pettigrew 2003; Sheppard and Pettigrew 2006; Miller et al. 2000) conjectured the existence of a single oscillator external to the level of sensory representation that drives the switches, based on their results showing strong correlations of switch rates across subjects for different visual bistable stimuli. They proposed that oscillatory activity in the brainstem/subcortical area may generate rhythmic fluctuations in activity across the two cortical hemispheres. This would lead one to expect similar dynamics for bistable perception in different modalities. However, some studies reported absence of correlation across modalities for subject-specific biases (Pressnitzer and Hupé 2006; Carter et al. 2008).

Winnerless Competition Models

Winnerless competition models propose a mechanism for perceptual dynamics based on deterministic trajectories moving along heteroclinic orbits that connect saddle points in the phase space (Rabinovich et al. 2001). The saddles correspond to the activity of specific neurons or group of neurons and the heteroclinic orbits connecting the saddles correspond to the switches between different states. Winnerless competition models are not multistable; states are represented by transient trajectories close to the saddles rather than attractors of the noiseless system. The models can account for properties such as distribution of dominance times and Levelt's propositions (Ashwin and Lavric 2010).

Models of Percept Formation

Most models focus on the dynamics of perceptual alternations assuming that the percepts and their neuronal representations are given. Other models have been developed to account for the form of the generated percepts. Diekmann, Golubitsky, and Wang (2013) presented an algorithmic-like model based on Wilson's networks to account for interocular grouping percepts in binocular rivalry (Kovacs et al. 1996; Suzuki and Grabowecky 2002). These percepts are new images generated from features extracted from the images presented to the left and right eyes. The model considers neural populations that code for a particular image feature (such as color, orientation, motion direction, position, etc.). Neural populations that code for features of the presented images have excitatory connections. The model then looks for bifurcations from a fused state to an oscillatory state, in which several competing percepts alternate. They can also predict the form of the conflicting percepts, which in the case of interocular grouping contains features from both presented images.

In the auditory domain, Mill et al. (2013) proposed a model that looks for predictable patterns from the ongoing sequence of tones. These patterns are then strengthened or weakened based on their predictive success. The ones that are strengthened and thus maintained compete with other representations, creating perceptual multistability.

Perceptual Multistability with More Than Two Interpretations

Results on ambiguous sensory stimuli with more than two interpretations are still scarce in the literature. However, more than two percepts allow us to go beyond the temporal dynamics and explore transitions to different states. Recent results suggest that switches are not totally random but there is some dependence on perceptual history and/or trapping (Suzuki and Grabowecky 2002; Naber et al. 2010; Wallis and Ringelhan 2013; Huguet et al. 2014).

Multistability in Seizure Dynamics

Maxim Bazhenov and Giri P. Krishnan
Department of Cell Biology and Neuroscience,
University of California, Riverside, CA, USA

Definition

Several types of seizures manifest themselves in stereotyped patterns of electrical activity

characterized by large-amplitude periodic fluctuations of the local field potential (LFP), alternations of the spike/polyspike and wave (SW/PSW) EEG discharges, and fast runs of EEG spikes. Alternations between different types of activity over the course of a seizure may be explained by transitions between different states of the multistable dynamical system describing the brain network in the pathological epileptic condition. Furthermore, the epileptic state itself may represent one of many dynamical states, including a healthy state, which coexist in the same brain network. Thus, understanding the role of multistability is of tremendous importance for identifying the mechanisms and driving factors of epileptic seizures.

Detailed Description

Many types of epileptic seizures, including absence seizures, Lennox-Gastaut syndrome, West syndrome, and posttraumatic epilepsy (Niedermeyer 2005), are associated with spike/polyspike and wave (SW/PSW) complexes recurring at 2–3 Hz and/or fast runs at 10–15 Hz. The fast runs (or tonic state) and slow SW/PSW activity (or bursting state) commonly occur several times during seizure with spontaneous transitions between states (Fig. 1a). One duration estimate in animal models of a typical spike-wave seizure episode includes approximately 80% bursting activity and 20% of tonic spiking (Boucetta et al. 2008). Recordings from humans during epileptic seizures show evidence of multiple state transitions in self-terminating seizures (Schiff et al. 2005; Kramer et al. 2012).

Ionic concentrations may fluctuate significantly during seizure. Indeed, substantial fluctuations of extracellular K^+ concentration ($[K^+]_o$) were found during electrically or pharmacologically induced paroxysmal activity (Heinemann and Lux 1977). Extracellular Na^+ concentration ($[Na^+]_o$) decreases during epileptiform activity (Somjen 2002), which likely corresponds to increase of $[Na^+]_i$. Depolarizing effects of GABA-A receptor activation during seizure suggest elevated levels of intracellular Cl^- concentration ($[Cl^-]_i$) (Timofeev et al.

Multistability in Seizure Dynamics, Fig. 1 (a) Following transient (red line) DC stimulation, membrane voltage of a single pyramidal neuron from the network revealed several state transitions between tonic (fast runs) and clonic (bursting) periods before spontaneous termination. Bottom plots in (a) show activity of a pyramidal neuron for 2 s during bursting (green) and tonic periods (blue) (b) $[K^+]_o$, $[Na^+]_i$, and $[Cl^-]_i$ of one pyramidal neuron increased during tonic states and

decreased during bursting (c) Left, bifurcation diagram as a function of $[K^+]_o$ (minimum and maximum values of membrane voltage plotted as a function of parameter $[K^+]_o$). Solid lines indicate increasing $[K^+]_o$ and dashed lines for decreasing $[K^+]_o$. Insets show sample voltage traces for two values of $[K^+]_o$ (6.1 and 9.5 mM). Each plot was obtained for progressively increasing (left) and then decreasing (right) values of $[K^+]_o$. Gray region indicates existence of both tonic and bursting state or

2002). These changes in ion concentrations are observed experimentally and were also simulated in computer models (Fig. 1b). The ion changes may have profound effects on the network dynamics and may be responsible for the characteristic patterns of electrical activity observed during seizures.

Extracellular potassium concentration oscillates during seizure (Somjen 2002), a characteristic of the variable that determines state transitions. Application of dynamical system analysis to the study the role of $[K^+]_o$ in generating electrical patterns of activity during epileptic seizures revealed (1) the existence of four distinct activity patterns as a function of $[K^+]_o$, i.e., silence, tonic firing, bursting, and depolarization block, and (2) bistability with hysteresis between tonic firing and bursting for elevated $[K^+]_o$ levels (Frohlich and Bazhenov 2006; Frohlich et al. 2006, 2008). This bistability found by open-loop analysis of the models explains the occurrence of transitions between tonic firing and bursting (Fig. 1c, left). Specifically, neurons remained in tonic-firing mode, while $[K^+]_o$ increased up to the level where they were forced to switch to bursting mode (upper endpoint of hysteresis). Conversely, neurons remained in bursting mode, while $[K^+]_o$ decreased until the lower endpoint of the hysteresis was reached where they were forced to switch back to tonic-firing mode and the next cycle began. These modeling results show the alternating occurrence of positive (during tonic firing) and negative (during bursting) feedback. It suggests that transitions between tonic firing and bursting observed during many types of seizure may arise from the slow alternations between two metastable states, tonic firing and bursting states, mediated by $[K^+]_o$ dynamics.

In a network of neurons, bistability becomes critical in maintaining a stable seizure-like

state. However, in realistic conditions seizures spontaneously terminate within a few minutes. This can be explained by taking into account dynamics of other ion concentrations. Intracellular sodium ($[Na^+]_i$) progressively increases during a seizure episode due to spiking activity and the slow nature of Na^+ removal processes (Fig. 1b). This leads to a reduction of the resting membrane potential and increase in activity of the Na^+/K^+ exchange pump, which is electrogenic and mediates outward hyperpolarizing current. Both of these processes result in hyperpolarization of the membrane potential leading to termination of the seizure and start of the postictal depression state (Fig. 1a; Krishnan and Bazhenov 2011).

In terms of dynamical systems analysis, the slow increase of $[Na^+]_i$ during seizure leads to the disappearance of bistability which is required for self-sustained periodic transitions between tonic spiking and bursting, causing termination of the paroxysmal activity (Fig. 1c, right). Other studies have also reported transitions between different dynamical states due to change in ion concentrations in various classes of the model neurons (Cressman et al. 2009; Barreto and Cressman 2011).

Multistability between various seizure states can be mediated by other neuronal variables. Analysis of a leech neuron shows bistability exists between different tonic states (Cymbalyuk and Shilnikov 2005), tonic spiking and bursting states (Shilnikov et al. 2005), and between silence and bursting states (Malashchenko et al. 2011). In these studies, bistability was observed as a function of the reversal potential of potassium currents or external inputs. Detailed analysis of these models further revealed that bistability arises from the coexistence of stable periodic orbits (Cymbalyuk and Shilnikov 2005) or due to various bifurcation of periodic orbits (Shilnikov et al. 2005).

Multistability in Seizure Dynamics, Fig. 1 (continued) the bistable region. The tonic/bursting bistable region disappeared for sufficiently large values of $[Na^+]_i$. *Right*,

the same bifurcation diagram for slightly elevated $[Na^+]_i$. Note the disappearance of bistability

Ion concentration dynamics might explain not only transitions between different seizure states but also occurrence of the epileptic state itself (Frohlich et al. 2010). According to this hypothesis, the network can be in either the physiological or the pathological activity state. The relative size of the domain of attraction of the physiological state defines the resistance to seizure initiation. On the other hand, the relative size of the domain of attraction of the seizure state may define the intensity and duration of the individual seizures. These two domains of attractions will thus define if and how severely a brain will develop epileptic seizures. Patients suffering from epilepsy would have a reduced basin of attraction for the stable physiological state such that random input fluctuations can more easily cause a transition into the seizure state.

Experimental studies suggest that the balance of excitation and inhibition may change during the course of a seizure (Ziburkus et al. 2006, 2013), causing the basin of attraction of different dynamical states to change or even eliminate/create bistability. Existence of bistability due to the changes of excitation and/or inhibition has been shown in various types of neural mass models. In these studies, populations of neurons were reduced to a single equation (Lopes da Silva et al. 2003), and “normal” and “epileptic states” coexisted for the same sets of parameters. External inputs or internal random perturbations of the system determined the transition between normal and epileptic states.

In summary, the emergence of the network bistability proposes a fundamentally different viewpoint on how brain circuits can exhibit different activity states. In contrast to the commonly used approach of “parameter-mediated dynamic repertoire”, the dynamical richness of the neuronal circuit is not necessarily mediated by external, modulating factors but may be a direct consequence of dynamical mechanisms endogenous to the network.

Multistability of Coupled Neuronal Oscillators

Sorinel Adrian Oprisana

Department of Physics and Astronomy, College of Charleston, Charleston, SC, USA

Definition

The phase resetting curve (PRC) tabulates the transient changes in the firing period of an isolated neuron (*open-loop*) subject to an external stimulus identical to the one received when the neuron is part of a neural network (*closed loop*). The PRC is similar to a lookup table that gives the new firing period of a neuron in response to a specified perturbation applied at a given phase during the regenerative firing cycle. As such, the PRC contains all information needed to predict the response of a neural oscillator to a particular external perturbation. Under certain circumstances, networks of neural oscillators can develop stationary firing patterns called phase-locked modes. With appropriate external perturbations, a network can exhibit multistability and switch between different phase-locked modes. Memory storage and information processing are important examples of phase-locking processes that take place in neural networks. PRCs were used for the purpose of predicting the effects of

periodic stimuli to oscillating heart cells (Glass and Mackey 1988) and also for analyzing synchronization in systems of oscillators with pulsatile coupling (Winfree 1980; Glass and Mackey 1988; Reyes and Fetz 1993; Strogatz 2001; Pikovsky et al. 2003). The shape of the PRC determines the phase-locked modes and their sensitivity to noise and network heterogeneities (Tass 2007; Schultheiss et al. 2011).

Detailed Description

Among the techniques that are often used for predicting the activity of a neural network with the aid of a simplified model of individual neuron is the phase resetting curve (Tass 2007; Schultheiss et al. 2011). Both the phase resetting curve (PRC) and the spike time resetting curve (STRC) techniques reduce the complexity of a neuron to a black box whose output is a train of regular brief action potentials, or spikes, sensitive to the timing, or phase, of the external perturbations such as injected currents, presynaptic inputs, or neuromodulators (Oprisana and Boutan 2008; Oprisana 2009, 2010, 2014). The generality of both the PRC and STRC techniques stems from the fact that they can be applied to heterogeneous networks and are not limited to small amplitude (Rinzel and Ermentrout 1998; Ermentrout 2002; Preyer and Butera 2005) or short duration (pulsatile, or instantaneous) couplings among neurons (Oprisana et al. 2004; Netoff et al. 2005). Moreover, the PRC and STRC methods can be used to predict phase-locked modes in neural networks even when explicit mathematical models of component neurons are not available (Oprisana et al. 2003; Kralemann et al. 2013).

Neural Excitability Classes and PRC Types

Neural excitability refers to the capability of a neuron to produce repetitive action potentials in response to an externally applied current. In their seminal work on a giant squid axon, Hodgkin and Huxley (Hodgkin and Huxley 1952a, b, c, d;

Hodgkin et al. 1952) experimentally identified three classes of axonal excitability: class 1, for which the repetitive firing is controlled by the intensity of an external stimulus and firing begins at arbitrarily low frequencies and increases as current increases; class 2, for which the repetitive firing starts at higher frequency range and the firing frequency change only marginally with increasing current; and class 3, for which there are no endogenous firing regardless of stimulus intensity or duration. The model neuron used in this entry is represented by the dimensionless equations of Morris-Lecar (ML) model neuron given at the end of the entry (Morris and Lecar 1981; Ermentrout 1996).

The class of membrane excitability is related to the mechanism underlying the transition from silence to oscillations. A gradual increase of a control parameter, such as the strength of an external bias current, could lead to a qualitative transition, or bifurcation, in the activity of the neuron (Ermentrout and Terman 2010). For example, a ML model neuron for which the bias current is between 0.02073 (SN₁ point in Fig. 1b) and 0.08326 (SN₂ point in Fig. 1b) has three steady states, of which only the lower fixed point (thick continuous line) is stable. At a bias current of 0.08326, marked by the vertical dashed line in Fig. 1b, i.e., the bifurcation point SN₂, the membrane potential suddenly starts large-amplitude oscillations, i.e., spiking between the $V_{\min}$ and

$V_{\max}$. At this bifurcation point, at least one eigenvalue of the linearized model neuron near the critical (bifurcation) point becomes positive with all the other eigenvalues being real and negative. Such a bifurcation is called a saddle node and is traditionally associated with class 1 excitability (see Fig. 1b). The peak-to-peak amplitude of the stable limit cycle that emerges at SN₂ is represented by one solid circle on the lower ($V_{\min}$) branch and a corresponding solid circle on the upper ($V_{\max}$) branch of the bifurcation diagram shown in Fig. 1b. The stable limit cycle (solid circles) collides with the unstable limit cycle (open circles) that emerges from a subcritical Hopf (HB) for a current of 0.2038. At the Hopf bifurcation point, a pair of the eigenvalues of the linearized model neuron assumes pure imaginary values with all other eigenvalues being real and negative (see Fig. 1c). A supercritical Hopf bifurcation leads to stable limit cycle oscillations and is traditionally associated with class 2 excitability (Hoppensteadt and Izhikevich 1997; Izhikevich 2007).

As a rule of thumb, the neural oscillators that are near a saddle node on an invariant circle (SNIC) bifurcation (see Fig. 1b) produce unimodal, or type 1, PRCs (see Fig. 2b). When oscillations arise from a Hopf bifurcation (see Fig. 1c), the PRCs tend to be bimodal, or type 2 (see Fig. 2c). The above rule has its exceptions, e.g., a modified Poincaré model of an abstract

M

Multistability of Coupled Neuronal Oscillators,

Fig. 1 The frequency versus bias current curve for class 1 (solid circles) starts at arbitrarily small frequency, whereas for class 2 excitability (solid squares), the oscillations start at a nonzero frequency (a). The bifurcations diagram of a class 1 excitable ML model has a SNIC bifurcation point at SN₂ for a current of 0.08326 (b). The continuous/dashed lines represent stable/unstable steady

states. Stable limit cycle oscillations have peak-to-peak amplitude between pairs of solid circles on lower ($V_{\min}$) and upper ($V_{\max}$) branches of the bifurcation diagram. Unstable limit cycle oscillations emerge from a subcritical Hopf bifurcation (HB) for a current of 0.2038. Stable oscillations of a class 2 excitable ML model emerge via supercritical HB (c)

Multistability of Coupled Neuronal Oscillators, Fig. 2 Repetitive firing of a model neuron (*dashed line*) is briefly perturbed at stimulus time t_s (*continuous line*), and the firing period changes from the intrinsic value P_i to P_1 during the current cycle that includes the perturbation (a). The stimulus time, t_s , represents the time elapsed between an arbitrarily phase reference and the activation of the

external stimulus. Alternatively, a stimulus phase variable could be used $\varphi = t_s/P_i$. The recovery time, t_r , is the elapsed between the stimulus activation and the next crossing of the phase reference. The first-order PRC is the normalized change in the firing period, i.e., $F^1(\varphi) = (P_1 - P_i)/P_i$, and can have unimodal shape for type 1 PRCs (b) or bimodal shape for type 2 PRCs (c)

oscillator near a SNIC bifurcation that can produce bimodal PRCs (Schultheiss et al. 2011; Ermentrout et al. 2012; Oprisan 2013).

Mathematical Definition of the PRC and the STRC

The intrinsic, or free-running, period P_i of a neural oscillator is the time interval between two successive crossings of an arbitrary membrane voltage threshold with the same slope in the absence of any external perturbation (Fig. 2a). External stimuli induce transient changes in the firing period that could be captured by the PRCs (Tass 2007; Schultheiss et al. 2011) or the STRCs (Kopell and Ermentrout 1988; Oprisan and Boutan 2008; Oprisan 2010, 2014). The largest change in the transient period of oscillation occurs during the current cycle, P_1 , i.e., the cycle that includes the perturbation, and is measured by the first-order PRC (Fig. 2a). Long-lasting transient changes of the intrinsic firing period, P_i , can be captured by measuring the interspike intervals of the subsequent cycles, P_2 , P_3 , etc. The stimulus time, t_s , represents the time elapsed between an arbitrarily phase reference and the activation of the external stimulus. The stimulus phase is the normalized stimulus time $\varphi = t_s/P_i$. The stimulus time is the duration between the most recent crossing of an arbitrary voltage threshold with positive slope, i.e., phase reference, and the onset of the stimulus. In this entry, the phase reference was set by a

crossing of $V_{thr} = 0$ mV voltage threshold with a positive slope (Fig. 2a). For example, the first-order transient PRC is defined by

$$F^1(\varphi) = P_1/P_i - 1, \quad (1)$$

where P_1 is the transiently modified firing period of the current cycle and $F^1(\varphi)$ measures the relative advance, if $F^1(\varphi) < 0$, or delay, if $F^1(\varphi) > 0$, of the subsequent spike due to a perturbation applied at phase φ during the current cycle.

The STRC keeps track of the recovery time t_r , i.e., how long it takes the neuron to recover from the most recent external input and fire again, and conveniently plots it versus the stimulus time t_s (Fig. 3a, b; Kopell and Ermentrout 1988; Galan et al. 2005; Oprisan and Boutan 2008; Oprisan 2010):

$$t_r = f(t_s) \quad (2)$$

The first-order PRC and the STRC are mathematically related. Indeed, from Fig. 2a, it results that $P_1 = t_s + t_r$, which, leads to

$$t_r = P_1 - t_s = P_1 - \varphi P_i \quad (3)$$

By substituting the definition Eq. 1 of the PRC, $P_1 = (1 + F^1(\varphi))P_i$, into Eq. 3,

$$t_r = P_i(1 - \varphi + F^1(\varphi)) = f(t_s), \quad (4)$$

which explicitly describes the relationship between the first-order PRC, $F^1(\varphi)$, and the

Multistability of Coupled Neuronal Oscillators,

Fig. 3 The STRC of type 1 (a) and type 2 (b) with the intrinsic period of 30 ms (continuous curve). The dashed line represents the curve of no phase resetting, i.e., $t_r = P_i - t_s$

corresponding STRC, $f(t_s)$. Therefore, all mathematical criteria for the existence and stability of phase-locked modes using the first-order PRC can be immediately expressed in terms of the STRC. Higher-order PRCs break the equivalence between the two approaches (Schultheiss et al. 2011). If there is no resetting, i.e., $F^1(\varphi) = 0$, then the STRC curve becomes $f(\varphi) = P_i(1 - \varphi)$, which is the dashed line of no resetting shown in Fig. 3.

Notation

The PRC order is always shown as an upper numerical index, e.g., F^1 is the first-order PRC. The corresponding neuronal oscillator is identified by a lower numerical index, e.g., t_{s1} refers to the stimulus time t_s of the input received by neuron “1” and P_{12} refers to the transiently modified period of the current cycle P_1 for the neuron labeled “2.” Open brackets () are reserved for functional arguments, as in $F(\varphi)$ or $f(t)$, whereas closed brackets [] label the firing cycle counted from an arbitrary reference.

Assumptions and Limitations of PRC Method

Shape Invariance

Both the PRC and the STRC methods predict the phase-locked firing patterns of neural networks using the response of an isolated neuron, i.e., open-loop setup, to an injected stimulus identical to the one received by the same neuron when it is fully connected, i.e., closed-loop setup. However, the actual shape of a presynaptic input is determined by both neuron’s intrinsic dynamics and its

environment. As a result, stylized shapes of the presynaptic inputs such as infinitesimally short pulsatile currents and rectangular- or triangular-shaped presynaptic inputs are often used (Gerstner and Kistler 2002; Ermentrout and Terman 2010; Schultheiss et al. 2011).

Attractive Limit Cycles

In practice, a neuron receives a stimulus at a given phase, and its response is recorded in order to determine the PRC. After 4–5 cycles, another perturbation is applied at a different phase and the response is recorded again and so on. The 4–5 cycles between successive perturbations allow the neuron to return to its unperturbed free-running state (Cui et al. 2009; Netoff et al. 2012). However, when using the PRC for the purpose of predicting the phase-locked modes of the network, the neuron receives one (or more) presynaptic input(s) every cycle. As a result, there is an implicit assumption that neural oscillators return to the unperturbed state in one cycle, i.e., the limit cycle strongly attracts any state space trajectory. This assumption can be relaxed by considering the effect of higher-order PRCs.

Instantaneous Resetting

Somewhat related to the high convergence rate of state space trajectories to the unperturbed limit cycle is the assumption that the effect of a stimulus is only captured by the (first-order) PRC, i.e., the resetting happens instantaneously. This assumption is problematic for perturbation that has a finite duration, especially when the perturbation is applied toward the end of the

cycle and spans two cycles. The issue can be alleviated by considering higher-order PRCs (Oprisan 2010; Schultheiss et al. 2011).

Single Input per Cycle

Finally, depending on the topology of the network, some neurons may receive multiple inputs per cycle, which are handled by a special form of the PRC (Oprisan and Canavier 2003, Oprisan 2012b), which is outside of the scope of this entry. Rings with neurons with appropriate periods of oscillations of individual oscillators allow only one input per cycle and can be solved with the traditional PRC technique described in this entry. Such networks were extensively studied as model neural circuits mimicking central pattern generators controlling legged locomotion (Pavlidis 1973; Golubitsky et al. 1998, 1999; Buono 2001; Nakanishi et al. 2004; Tass 2007; Proctor and Holmes 2010; Proctor et al. 2010; Schultheiss et al. 2011).

Phase-Locked Modes in Half-Centers

Although the PRCs and STRCs can be used to study arbitrarily large ring networks, we only refer here to two-neuron networks, or half-centers, due to their biological relevance. *Half-centers* are reciprocally inhibitory functional antagonists leading to an alternating activity pattern (Brown 1914). Half-centers rely on tonic external stimuli to trigger oscillations or to set the appropriate frequency of the rhythm, or they rely on exogenous rhythmic input, as in the case of pyloric network of the lobster stomatogastric nervous system (Harris-Warrick et al. 1992; Chow et al. 2005). Other well-studied half-centers control the leech's heartbeat (Calabrese et al. 1995; Efimov 2011), crab's stomatogastric (STG) nervous system (Bartos et al. 1999; Thuma et al. 2003), and lobster's STG (Harris-Warrick et al. 1992; Marder and Bucher 2001; Hooper and DiCaprio 2004; Marder and Bucher 2007). In addition, larger networks often can be divided into loosely connected half-centers (Skinner et al. 1994; Marder and Bucher 2001). Therefore, predicting firing patterns of half-

centers based on the intrinsic properties of individual oscillators and their connections is biologically relevant.

Throughout this entry, we will use a biophysically relevant, yet low-dimensional, neural oscillator model developed by Morris and Lecar (ML) to mimic the action potentials in barnacle muscle (Morris and Lecar 1981; Ermentrout 1996). In addition, ML model has the advantage that it can switch from class 1 to class 2 excitability by changing the values of only a few control parameters (see the "Model section for a detailed mathematical model").

Coupling spiking neurons through fast synapses produces brief synaptic currents that induce soft resetting. Such brief synaptic inputs change the firing period of the postsynaptic neuron, and their effect can be captured entirely by the first-order PRC or, equivalently, by the STRC. The advantage of the STRC-based prediction of phase-locked modes over the first-order PRC method consists of a straightforward geometric interpretation.

In a two-neuron network of reciprocally coupled spiking neurons, the recovery time of one neuron is the same as the stimulus time of the other neuron (Fig. 5):

$$t_{s1}[n] = t_{r2}[n-1] \& t_{s2}[n] = t_{r1}[n] \quad (5)$$

Using the STRC definitions from Eq. 2, the recovery time can be written in terms of the stimulus time for the same neuron, i.e., $t_{r2}[n-1] = f_2(t_{s2}[n-1])$ and $t_{r1}[n] = f_1(t_{s1}[n])$. By substituting these definitions into Eq. 5, one finds

$$t_{s1}[n] = f_2(t_{s2}[n-1]) \& t_{s2}[n] = f_1(t_{s1}[n]), \quad (6)$$

which after substituting the second equation of Eq. 6 into the first one gives the *recursive existence criterion for 1:1 phase-locked modes*:

$$t_{s1}[n] = f_2(f_1(t_{s1}[n-1])), \quad (7)$$

which determines the n th cycle's stimulus time based on its value during the previous cycle. The fixed points of Eq. 7 determine the phase-locked stimulus time:

$$t_{s1}^* = f_2(f_1(t_{s1}^*)) \quad (8)$$

The geometrical interpretation of the existence criterion given by Eq. 8 is as follows. Normally, the STRC, i.e., $t_r = f(t_s)$, is represented with the recovery time, t_r , along the vertical axis and the corresponding stimulus time, t_s , along the horizontal axis (see Fig. 3). However, in order to fulfill the mathematical condition for phase-locked modes, i.e., the stimulus time of one neuron must be equal to the recovery time of the other neuron (see Eq. 5), the axes of the STRC of the second neuron are flipped (Schultheiss et al. 2011; Oprisan 2012a, b). Indeed, in Fig. 5a we plotted the STRC of neuron “1” (continuous line) with the recovery time on the vertical axis and the stimulus time along the horizontal axis. The STRC of neuron “2” was plotted with the axes flipped, i.e., the recovery time along the horizontal axis and the stimulus time along the vertical. Therefore, the crossing point of the two STRCs satisfies the condition that $t_{s1} = t_{r2}$, which is the phase-locked existence criterion given by Eq. 5. In Fig. 5 we used an asymmetric coupling of two identical type 1 ML model neurons with synaptic couplings $g_{2 \rightarrow 1} = 0.010$ a.u., $g_{1 \rightarrow 2} = 0.015$ a.u. The predicted 1:1 phase-locked mode is $t_{s1}^* = 8.5$ ms and $t_{s2}^* = 23.5$ ms (Fig. 5a).

According to the STRC-based existence criterion given by Eq. 8, it is possible to have multiple intersections of the two STRCs of which some will be stable and other unstable. To determine the stability of a phase-locked mode to small perturbations, let us assume small deviations, $\delta t_{s1}[n]$, of the stimulus time from its steady-state (phase-locked) value, t_{s1}^* , predicted by the existence criterion (see Eq. 8). First, let us estimate the effect of small perturbation on $f_1(t_{s1}[n-1])$ and then use the result to determine how that perturbation propagates to the next recursion cycle that determines the existence of phase-locked modes according to Eq. 7, i.e., $t_{s1}[n] = f_2(f_1(t_{s1}[n-1]))$. For small perturbations, i.e., $|\delta t_{s1}[n]| \ll t_{s1}^*$, the Taylor's expansion around t_{s1}^* is

$$\begin{aligned} f_1(t_{s1}[n-1]) &= f_1(t_{s1}^* + \delta t_{s1}[n-1]) \\ &= f_1(t_{s1}^*) + \partial f_1 / \partial t_{s1}^* \delta t_{s1}[n-1] \\ &\quad + o(\delta t_{s1}[n-1]^2) \\ &\approx t_{s2}^* + n_1 \delta t_{s1}[n-1] \end{aligned} \quad (9)$$

where n_1 is the slope of the STRC of the first neuron at steady state. By substituting Eq. 9 into Eq. 7, one gets

$$\begin{aligned} t_{s1}[n] &= f_2(f_1(t_{s1}[n-1])) \\ &\approx f_2(t_{s2}^* + n_1 \delta t_{s1}[n-1]) \\ &= f_2(t_{s2}^*) + \partial f_2 / \partial t_{s1}^* n_1 \delta t_{s1}[n-1] \\ &\quad + O(\delta t_{s1}[n-1]^2) \approx t_{s1}^* \\ &\quad + n_2 n_1 \delta t_{s1}[n-1] \end{aligned} \quad (10)$$

Based on the linear stability analysis above, the error on the stimulus time during the n th cycle, $\delta t_{s1}[n]$, is related to its error during the previous cycle by

$$\begin{aligned} \delta t_{s1}[n] &= n_2 n_1 \delta t_{s1}[n-1] \\ &= \lambda_{\text{STRC}} \delta t_{s1}[n-1], \end{aligned} \quad (11)$$

which is the *STRC-based recursive stability criterion*. The solution of Eq. 11 is $\delta t_{s1}[n] = \lambda_{\text{STRC}}^n \delta t_{s1}[0]$ and describes the evolution of a small perturbation $\delta t_{s1}[0]$ from the steady-state t_{s1}^* , which is the phase-locked mode, over n cycles. The 1:1 phase-locked mode is stable if the stability index $|\lambda_{\text{STRC}}| = |n_2 n_1| < 1$.

The above STRC-based existence and stability criteria for phase-locked modes can be also expressed using PRC and Eq. 4, i.e., $P_i(1 - \varphi + F^1(\varphi)) = f(t_s)$. For example, Eq. 6 becomes

$$\begin{aligned} (\varphi_2[n-1]P_{i2}) &= P_{i2}(1 - \varphi_2[n-1] + F_2^1(\varphi_2[n-1])), \\ \varphi_1[n]P_{i1} &= P_{i1}(1 - \varphi_1[n] + F_1^1(\varphi_1[n])), \end{aligned} \quad (12)$$

which can be solved as before by substituting the second Eq. 12 into the first one. Based on Eq. 12, the phase-locked mode for identical oscillators, i.e., $P_{i1} = P_{i2}$, becomes

$$\begin{aligned}\varphi_1^* &= 1 - \varphi_2^* + F_2^1(\varphi_2^*), & \& \\ \varphi_2^* &= 1 - \varphi_1^* + F_1^1(\varphi_1^*),\end{aligned}$$

which can be written as

$$\varphi_1^* + \varphi_2^* - 1 = F_2^1(\varphi_2^*) = F_1^1(\varphi_1^*) \quad (13)$$

The geometric interpretation of the PRC-based existence criterion for identical neurons given by Eq. 13 involves finding all pairs $(\varphi_1^*, \varphi_2^*)$ that satisfy $F_2^1(\varphi_2^*) = F_1^1(\varphi_1^*) = F^*$ (see the horizontal dashed line in Fig. 5b) and only retaining those for which $\varphi_1^* + \varphi_2^* - 1 = F^*$. In the abovementioned asymmetrically coupling of two neurons with synaptic couplings $g_{2 \rightarrow 1} = 0.010$ a.u., $g_{1 \rightarrow 2} = 0.015$ a.u. gives the steady-state phases $\varphi_1^* = 0.82$, which corresponds to $t_{s1}^* = \varphi_1^* P_{i1} = 0.82 * 28.8 \text{ ms} = 23.6 \text{ ms}$, and $\varphi_2^* = 0.27$, which corresponds to $t_{s2}^* = \varphi_2^* P_{i2} = 0.27 * 28.8 \text{ ms} = 7.8 \text{ ms}$.

The PRC-based stability criterion can be immediately determined based on the STRC-based stability criterion Eq. 11 and the relationship between the PRC and STRC (see Eq. 4). Indeed, from Eq. 4 it results that the relationship between the slopes of PRCs and STRCs is

$$\begin{aligned}d(1 - \varphi + F^1(\varphi))/d\varphi &= d(f(t_s))/dt_s \\ \Leftrightarrow m - 1 &= n,\end{aligned} \quad (14)$$

which when substituted into Eq. 11 leads to

$$\begin{aligned}\delta\varphi_1[n] &= (m_2^1 - 1)(m_1^1 - 1)\delta\varphi_1[n-1] \\ &= \lambda_{\text{PRC}}\delta\varphi_1[n-1],\end{aligned} \quad (15)$$

where the stability index is $\lambda_{\text{PRC}} = (1 - m_1^1)(1 - m_2^1)$ and m_k^1 is the slope of the first-order PRC for neuron k . The phase-locked mode is stable to small perturbations if the PRC-based stability index $|\lambda_{\text{PRC}}| = |(1 - m_1^1)(1 - m_2^1)| < 1$. For identical neurons, the PRC-based stability criterion is $(1 - m)^2 < 1$, which leads to $0 < m < 2$ (Schultheiss et al. 2011).

The above predictions based on the STRC (see Fig. 5a) gave us steady spike times $t_{s1}^* = 8.5 \text{ ms}$ and $t_{s2}^* = 23.5 \text{ ms}$. Similarly, using the PRC

method (see Fig. 5b), we predicted for the same half-center the steady phase that $\varphi_1^* = 0.82$, which corresponds to $t_{s1}^* = \varphi_1^* P_{i1} = 0.82 * 28.8 \text{ ms} = 23.6 \text{ ms}$, and $\varphi_2^* = 0.27$, which corresponds to $t_{s2}^* = \varphi_2^* P_{i2} = 0.27 * 28.8 \text{ ms} = 7.8 \text{ ms}$.

The above predictions were made in open-loop setup, and we also tested the phase-locked mode in closed loop. For this purpose, we coupled two identical type 1 ML model neurons with an instantaneous synaptic current $I_{\text{syn}} = g_{\text{syn}}(V_{\text{pre}} - E_{\text{syn}})$, where V_{pre} is the membrane potential of the presynaptic neuron and E_{syn} is the reversal potential of the synapse (Oprisan and Boutan 2008; Oprisan 2010; Schultheiss et al. 2011). All open-loop predictions were in very good agreement with closed-loop numerical simulations. For example, Fig. 5c shows the firing pattern of the half-center in closed loop with a stable stimulus time $t_{s1} = 21 \text{ ms}$ and a recovery time $t_{r1} = 12 \text{ ms}$.

Multistability in Half-Centers with Phase Resetting Curve

Coupled oscillators often develop more complex phase-locked modes, such as $m:n$ firing, which is a stable firing pattern that repeats after the first neuron completed m cycles and the second neuron completed n cycles. Prominent examples of $m:n$ phase-locked modes include the 4:1 phase-locked mode between the heart beats and the respiratory cycle (Seidel and Herzog 1998; Schafer et al. 1998), motor patterns (von Holst 1939), and voice modulation (Mergell et al. 2000). The existence and stability criteria developed in the previous sections can be used to predict the circumstances that can force a half-center to change its firing pattern, for example, from 1:1 to 1:2. Although the PRC can be used to investigate multistability and phase-locked mode instabilities for more general network architectures, we will only give the highlights of the application to entrainment, i.e., the case when one neuron, such as neuron “2” in Fig. 4, only drives a second neuron, such as neuron “1,” and the feedback loop is absent. Based on the definition given in Eq. 4, the recovery time of the driven neuron is.

Multistability of Coupled Neuronal Oscillators, Fig. 4 A schematic representation of a half-center network with two reciprocally inhibiting neurons, labeled “1” and “2” (left panel). Temporal evolution of a 1:1 firing pattern (right panel). The action potential generated by each neuron is marked by vertical thick rectangle and the

solid vertical arrows marks the moment the presynaptic neuron generates an action potential and sends an inhibition to its postsynaptic neuron. The recovery interval for the postsynaptic neuron t_r is the same as the stimulus time t_s of the presynaptic neuron

Multistability of Coupled Neuronal Oscillators, Fig. 5 Phase-locked mode prediction using STRC and PRC methods. (a) The STRC plot, i.e., t_{r1} versus t_{s1} , of the first neuron (continuous line) overlapped with the STRC plot of the second neuron (long dashed line) with the axes flipped, i.e., t_{s2} versus t_{r2} . The crossing point of the two STRCs is the fixed point of the recursive existence criterion given by Eq. 8 and represents the phase-locked mode of the network. (b) For each acceptable value F^*

(horizontal dashed line) of the phase resetting, there are two pairs of phases (φ_1, φ_2) that satisfy the existence criterion $F^* = F_2^1(\varphi_2^*) = F_1^1(\varphi_1^*)$. One pair of phases (φ_1, φ_2) would determine a stable phase-locked mode (solid circles), and the other leads to an unstable solution. (c) Actual recordings of membrane voltage traces of the two coupled neurons confirm that predicted phase difference with both STRC (a) and PRC (b) methods

$$t_{r1} = P_{i1}(1 - \varphi + F^1(\varphi)) \quad (16)$$

In general, for 1:1 entrainment (see Fig. 4), the driven neuron, i.e., “1,” should recover from the inhibition induced by the driving neuron “2” before it receives another input from the driving neuron. Mathematically, the above condition for 1:1 entrainment means that $t_{r1} \leq P_{i2}$. If $t_{r1} \geq P_{i2}$, then the driven neuron “1” receives two inputs

from the driving neuron “2” during the same cycle and the network switched to 1:2 entrainment. The marginal stability condition for 1:1 entrainment is

$$t_{r1} = P_{i1}(1 - \varphi + F^1(\varphi)) = P_{i2} \quad (17)$$

The above stability condition can be solved numerically to find the entrainment phase φ at

which the network develops multistability and switches from 1:1 to 1:2 modes. Alternatively, we could use an analytical expression for the PRC, if known, and solve Eq. 17. For example, in case of a SNIC bifurcation that is characteristic for class 1 excitability and that is usually associated with a unimodal PRC (see Fig. 2b), the analytic approximation for the infinitesimal PRC is (Izhikevich 2007; Ermentrout and Terman 2010; Schultheiss et al. 2011)

$$(F^1(\varphi)) = c (1 - \cos(\varphi)), \quad (18)$$

where c is a parameter that depends on the strength of the perturbation and the intrinsic firing period of the neuron receiving the perturbation. Additionally, if $c > 0$ the PRC is positive, which means that the subsequent spike is delayed by a perturbation, otherwise the spike is advances. By substituting Eq. 18 into Eq. 17,

the marginally stable phase of 1:1 entrainment can be determined for any given coupling strength, c , and intrinsic period ratio $p = P_{2i}/P_{1i}$ (see Fig. 6). For example, if the driving neuron has an intrinsic period P_{2i} three times as large as the driven neuron, i.e., $p = P_{2i}/P_{1i} = 3$ (dashed-dotted line in Fig. 6), then entrainment is only possible if the coupling strength is larger than a minimum, $c_{\min}$, required value able of forcing the follower to delay its next spike in order to match the driving neuron's intrinsic period. We also noticed that for each coupling strength that is able to produce a 1:1 entrainment, there are two possible values of the entrainment phase, which are almost symmetric with respect to the perfectly antiphase mode, i.e., phase = 0.5. In the case the driving neuron with intrinsic period P_{2i} is faster than the follower, i.e., $p = P_{2i}/P_{1i} < 1$, the 1:1 entrainment is only possible if the follower

Multistability of Coupled Neuronal Oscillators, Fig. 6 The 1:1 entrainment phase of a SNIC oscillator for which period ratio $p = P_{2i}/P_{1i}$ between the driving neuron (intrinsic period P_{2i}) and the follower (intrinsic period P_{1i}) is between 1 and 2 smoothly changes with the strength of the coupling and there is no bistability. A positive coupling constant means a positive PRC, i.e., a delay in the subsequent spike. For very dissimilar firing

periods, e.g., $p = 3$, a minimum coupling strength, $c_{\min}$, is necessary in order to delay the follower until it matches the driving neuron's intrinsic period. In this case, for each coupling strength, $c > c_{\min}$, there are two possible 1:1 phase-locked phases, i.e., the network shows bistability. Perturbations of the marginal 1:1 phase-locked modes can immediately lead to transitions from 1:1 to 1:2 firing patterns

can be advanced, i.e., the PRC is negative (see Fig. 6). For period ratios between 1 (continuous line in Fig. 6) and 2 (long dashed line in Fig. 6), there is only one possible entrainment (no multistability), and the phase difference between driving and follower linearly smoothly changes with the coupling strength. In conclusion, multistability emerges when the firing periods are very dissimilar ($p = P_{2i}/P_{1i} > 2$), and small perturbations at the marginal phases computed here can lead the neurons to switch from 1:1 to 1:2 phase-locked modes.

Conclusions

The bifurcation structure of a single cell (see Fig. 1) is the foundation for network-level multistability. We showed that, depending on the single-cell bifurcation structure, the response of a cell when it is part of a network, i.e., its phase response curve (see Fig. 2), has different degrees of bimodality. Type 1 PRCs are unimodal and allow only advance or delay of the subsequent action potential in response to a presynaptic input. Type 2 PRCs are bimodal and allow neurons to fine-tune their response until they “resonate” with a stable firing pattern of the network. While a PRC tabulates the response of a neuron in terms of phase of oscillation, the STRC (see Fig. 3) contains similar information in terms of stimulus and response times. The PRC is a powerful and versatile method that allows us to predict both the existence and the stability of phase-locked modes in neural networks. PRC- and STRC-based stability criteria for phase-locked modes allow us to predict when a firing pattern changes its stability and leads to multistability. For half-centers (see Fig. 4), both PRC and STRC methods give accurate and identical predictions, although the STRC-based method is slightly easier to apply and has a simpler geometrical interpretation (see Fig. 5). We also showed that the multistability of half-centers is controlled by both the intrinsic properties of the coupled neurons, such as their intrinsic firing periods, and the synaptic coupling strengths (see Fig. 6).

Appendix: Morris-Lecar Model

All numerical simulations were carried out with a conductance-based model that mimics the model giant barnacle muscle fiber (Morris and Lecar 1981). The model’s equations are

$$\begin{aligned}CdV/dt &= -g_{Ca}m_0(V - V_{Ca}) - g_Kw(V - V_K) \\ &\quad - g_L(V - V_L) + I, \\ dw/dt &= \phi(w_0 - w)/\tau_w,\end{aligned}$$

where the steady state values for Ca^{++} , i.e., $m_0 = (1 + \tan h((V - V_1)/V_2))/2$, and K^+ , i.e., $w_0 = (1 + \tanh((x - V_3)/V_4))/2$, are given by sigmoidal functions, and $\tau_w = 1/\cosh((V - V_3)/(2V_4))$ (Table 1).

All voltages are normalized by $V_0 = 120$ mV. The reversal potentials are $V_K = -0.7$, $V_L = -0.5$, and $V_{Ca} = 1.0$. The model’s constants are $V_1 = -0.01$ and $V_2 = 0.15$. The normalization constant for the conductances is $g_0 = 4$ mS/cm², and for the currents it is $V_0g_0 = 480$ μ A/cm².

The Mathematica code that implements the above ML model is the following:

Definition

Dynamical systems describe orbits or trajectories as they evolve in time-space. The brain is a dynamical system whose macroscopic behavior may be couched in terms of normal (e.g., waking, attentive, etc.) or abnormal (e.g., coma, seizure or post-seizure, etc.) states. Brain stability may be defined as the proneness of a trajectory or orbit to remain in its “neighborhood” in the presence of perturbations. The terms bistability and multistability denote the coexistence of more than one simultaneously “stable” states in a system.

Epilepsy is a disorder characterized by the aperiodic emergence of unprovoked seizures that in 20–40% of sufferers are uncontrollable by medications. Behaviorally, seizures are characterized by one or more of involuntary movements, sensations, perceptions, and loss of awareness or of consciousness. Electrically, seizures manifest as aberrant increases in power of neuronal oscillations at certain frequencies. Subjects with pharmaco-resistant seizures require special forms of therapy such as resection of epileptogenic brain tissue or electrical stimulation delivered to the said tissue. Electrical stimulation for seizure blockage has been traditionally delivered in pulse trains lasting for at least 1 s at frequencies rarely below 50 Hz (Lesser et al. 1999; Osorio et al. 2005). Seizure blockage using a single electrical pulse or at most a handful (e.g., up to 6) of pulses was attempted in vivo.

Multistability: Stopping Events with Single Pulses

Synonyms

Bistability; Flip-flop; Systems with two or more phase-spaces

Detailed Description

Seizure blockage using exogenous means such as a *single* electrical pulses is feasible only if neuronal oscillators behaving pathologically possess and may be forced into a “non-seizure well.” The existence of “non-seizure wells” or of non-seizure phase spaces for pathological neuronal oscillations (e.g., epileptic seizures) and the dynamics of the seizure (ictus) to non-seizure (postictal) transition were studied in animals whose brains (in whole or in part) had been rendered seizure prone with systemically or topically administered compounds (Osorio and Frei 2009).

Seizure blockage (or induction) was attempted with either single (or with up to 6) monophasic (DC) square wave pulses whose blocking (or triggering) efficacy was optimized by varying their intensity and polarity.

Single or few (up to 6) DC pulses (1.0–8.0 V; width: 100–200 μ s; electrode impedances: $\sim$ 1 K Ω) were delivered manually or automatically to (a) generalized tonic-clonic seizures, induced in rats with 3-mercaptopropionic acid, a GABA synthesis inhibitor, or (b) to a small region of

disinhibited (by topical application of penicillin, a GABA receptor antagonist) rabbit's cortex. Treatment outcome (blocked vs. non-blocked seizures) was investigated using the degree of morphological similarity among waves ("rhythmicity index"), an indirect measure of neuronal synchrony level. Blockage using single or brief (0.1 s) DC pulses was consistently achieved for seizures with a rhythmicity index >0.7 , while seizures with levels <0.6 were largely unperturbed (Fig. 1).

Multistability: Stopping Events with Single Pulses, Fig. 1 (a) Top left-hand panels depict six seizures recorded from one (representative) rat using subdural electrodes (activity from only one contact is shown) each treated with a total of 6 monophasic (cathodal) pulses delivered through the electrodes adjacent to those used for recording. (b) Top right-hand panels depict two seizures treated with single monophasic (cathodal) pulses (5 mA, 100 μ s) also delivered adjacent to the recording electrodes (same rat). The numbers on top of each tracing

to the left of the stimulation artifacts in each panel correspond to the "rhythmicity index," a measure of similarity between successive signal waveforms, computed using software developed by these investigators. (c) Magnified view of 6 tissue impulse responses to each of the 6 monophasic pulses delivered over 0.12 s to seizure #6. The probability of seizure blockage is clearly a function of rhythmicity index value. The impulse responses to cathodal stimulations show subtle phase changes (resetting) on their "way to the 'null space'"

The capacity of a single electrical pulse to either block (Figs. 1 and 2) or trigger (figure not shown) epileptic seizures may be construed as evidence of multistable dynamics in rodents' and lagomorphs' brains and by inference in those of humans with epilepsy. The dependence of probability of blockage on neuronal synchronization level is indicative of its importance for treatment outcome.

Three observations in this study (Osorio and Frei 2009) of interstate transitions in the mammalian brain merit deliberation:

1. Seizures were blocked by more than one pulse (e.g., up to 6 monophasic pulses) (Fig. 1), but by a much lesser number of pulses than conventionally used (e.g., 50–300) (Lesser et al. 1999; Osorio et al. 2005); that a handful (e.g., up to 6) instead of a single electrical pulse may under certain conditions be required to block seizures (Fig. 1) hints at the state-dependent existence of multiple “well potentials” between the ictal and postictal states.
2. Seizure blockage is dependent on pulse polarity; changing the polarity from positive to negative (or vice versa) may lead to failure

of blockage, an observation that insinuates that these phase-spaces have distinct “spatial orientations.”

3. The transition associated with seizure blockage is to another *abnormal* state, the so-called post-ictal, and not to the normal or interictal phase-space; exogenous or spontaneous termination of seizures does not immediately restore functional normalcy to the brain or more specifically to the networks engulfed by paroxysmal electrical activity as evidenced using spectral and clinical analyses.

A sudden highly desirable transition from an ictal to an interictal/normal space seems elusive, an indication that the dynamics of this transition are qualitatively different from that of the interictal to interictal phase-space or “well.”

While premature transitions (as required for clinical usefulness) from the ictal to the postictal “well” require some form of exogenous energy to violate the laws (Osorio et al. 2009, 2010) governing the intensity, duration, and extent of spread of pharmaco-resistant seizures, this transition occurs spontaneously, that is, in the absence of identifiable exogenous energy. The proclivity

Multistability: Stopping Events with Single Pulses, Fig. 2

To investigate if single DC pulses (1.0 ma; 500 us) were annihilating seizures, they were delivered to every other seizure, during a period when their morphology and duration were quite similar. Seizures are annihilated by single monophasic pulses

of the brain to transition between and within normal and abnormal phase-spaces without large energy expenditures may be observed in systems near the edge of stability.

For simplicity and for the sake of didactics, the epileptic brain may be conceptualized by resorting to the standard “double-well” potential (interictal and ictal) model (Fig. 3). In this model, the two minima (or “wells”) are stable phase-spaces, and only the maximum (e.g., the energy “barrier” between the 2 “wells”) is deemed unstable. The accepted dynamical description of a “double-well” potential is that, for example, stochastic perturbations force a “particle” that performs a “random walk” constrained by the well’s geometry toward the maximum; whether or not the “particle” returns to its original “well” (interictal) or is “forced” into the ictal (Fig. 3) depends on factors such as the magnitude, type, and timing of the perturbation, the height of the inter-well maxima, etc. While exogenous seizure blockage or generation (energy is required to “push” the particle out a well into another) may be adequately

Multistability: Stopping Events with Single Pulses, Fig. 3 Representation of three brain states (interictal, ictal, postictal) as “wells.” Transitions between states (e.g., from interictal to ictal) are indicated by arrows. The height of the inter-well separatrices (corresponding to voltage (V) barriers) varies as a function of level of consciousness, level and type of cognitive activity, time of day, stochastic factors (e.g., luminance level), etc., shaping interstate transition probabilities. Note that the transition from ictal to interictal requires passage through the post-ictal “well”

described by the two-well model, *spontaneous* interictal to ictal and ictal to postictal transitions in the epileptic brain may occur differently, and the epileptic brain may be better described by a *multi-* than a bistable paradigm as inferred from experimental observations by the group of Lopes da Silva. Indeed, the epileptic brain may be more aptly regarded as “multi-unstable” (e.g., far from stability).

Seizure blockage with a single (or a handful) of electrical pulses is not only a valuable therapeutic strategy but also a useful experimental tool that informs the scantily understood dynamics of the epileptic brain. Exploitation of “multistability” for therapeutic purposes is not modern; Pelops from Alexandria, the teacher of Galen, implemented this concept as early as 150 AD, using mechanical means (Siegel 1976).

Music Processing in the Brain

Stefan Kölsch
Department of Educational Science and
Psychology, Freie Universität Berlin, Berlin,
Germany

Definition

Music perception involves acoustic analysis, auditory memory, auditory scene analysis, processing of interval relations and of musical syntax and semantics, and activation of (pre)motor representations of actions. Moreover, music perception potentially elicits emotions, thus giving rise to the modulation of emotional effector systems such as the autonomic nervous system, the hormonal system, and the immune system. EEG and fMRI studies inform us about the time course of the processes underlying music perception, as well as about where in the brain these processes might be located.

Detailed Description

Introduction

Music has been proven to be a valuable tool for the understanding of human cognition, human emotion, and their underlying brain mechanisms. Music is part of the human nature: It appears that throughout human history, in every human culture, people have played and enjoyed music. The oldest musical instruments discovered so far are around 30,000–40,000 years old (Conard et al. 2009), but it is likely that already the first individuals belonging to the species *homo sapiens* made music (about 100,000–200,000 years ago). Only humans learn to play musical instruments, and only humans play instruments cooperatively together in groups. It is assumed by some that human musical abilities played a key phylogenetical role in the evolution of language (Wallin et al. 2000) and that music-making behavior engaged and promoted evolutionarily important social functions (Cross and Morley 2008; Koelsch 2014). Ontogenetically, newborns (who do not yet understand the syntax and semantics of words) are able to decode acoustic features of voices and prosodic features of languages (Moon et al. 1993), and it appears that infants' first steps into language are based in part on prosodic information (Jusczyk 1999). Moreover, musical communication in early childhood (such as parental singing) plays a major role in the emotional, presumably also in the cognitive and social development of children (Trehub 2003). Making music in a group is a tremendously demanding task for the human brain that elicits a large array of cognitive (and affective) processes, including perception, multimodal integration, learning, memory, action, social cognition, syntactic processing, and processing of meaning information. This richness makes music an ideal tool to investigate the workings of the human brain.

Auditory Feature Extraction

Music perception begins with the decoding of acoustic information. Acoustic information is translated into neural activity in the cochlea and progressively transformed in the auditory brainstem, as indicated by different neural

response properties for the periodicity of sounds, timbre (including roughness, or consonance/dissonance), sound intensity, and interaural disparities in the superior olivary complex and the inferior colliculus (Sinex et al. 2003; Langner and Ochse 2006; Pickles 2008; Geisler 1998). Already the dorsal cochlear nucleus projects into the reticular formation (Koch et al. 1992), and the vestibular nerve also contains numerous acoustically sensitive nerve fibers (Todd et al. 2014). Moreover, both the vestibular nuclei and cochlear nuclei project to the reticular formation, and the vestibular nucleus also projects to the parabrachial nucleus, a convergence site for vestibular, visceral, and autonomic processing. Such projections initiate and support movements and contribute to the arousing effects of music. Thus, subcortical processing of sounds gives rise not only to auditory sensations but also to muscular and autonomic responses, and the stimulation of motor neurons and autonomic neurons by low-frequency beats might contribute to the human impetus to “move to the beat.”

Further up in the auditory pathway, the inferior colliculi can initiate flight and defensive behavior in response to threatening stimuli (Lamprea et al. 2002; Cardoso et al. 1994). From the thalamus (particularly over the medial geniculate body), neural impulses are mainly projected into the auditory cortex (Kaas et al. 1999; LeDoux 2000; Öngür and Price 2000). Importantly, The auditory pathway does not only consist of bottom-up, but also of top-down projections; nuclei such as the dorsal nucleus of the inferior colliculus presumably receive even more descending than ascending projections from diverse auditory cortical fields (Huffman and Henson 1990).

During the last years, a number of studies investigated decoding of frequency information in the auditory brainstem using the frequency-following response (FFR). The FFR can be elicited preattentively and is thought to originate mainly from the inferior colliculus (but note also that it is likely that the auditory cortex is at least partly involved in shaping the FFRs, e.g., by virtue of top-down projections to the inferior colliculus). Using FFRs, Wong et al. (2007) measured brainstem responses to three Mandarin

tones that differed only in their (f_0) pitch contours. Participants were amateur musicians and nonmusicians, and results revealed that musicians had more accurate encoding of the pitch contour of the phonemes (as reflected in the FFRs) than nonmusicians. This finding indicates that the auditory brainstem is involved in the encoding of pitch contours of speech information (vowels) and that the correlation between the FFRs and the properties of the acoustic information is modulated by musical training. Similar training effects on FFRs elicited by syllables with a dipping pitch contour have also been observed in native English speakers (nonmusicians) after a training period of 14 days (Song et al. 2008). The latter results show the contribution of the brainstem in language learning and its neural plasticity in adulthood.

A study by Strait et al. (2009) also reported musical training effects on the decoding of the acoustic features of an affective vocalization (an infant’s unhappy cry), as reflected in auditory brainstem potentials. This suggests (a) that the auditory brainstem is involved in the auditory processing of communicated states of emotion (which substantially contributes to the decoding and understanding of *affective prosody*) and (b) that musical training can lead to a finer tuning of such (subcortical) processing.

Acoustical Equivalency of “Timbre” and “Phoneme”

With regard to a comparison between music and speech, it is worth mentioning that, in terms of acoustics, there is *no* difference between a phoneme and the timbre of a musical sound (and it is only a matter of convention that some phoneticians rather use terms such as “vowel quality” or “vowel color,” instead of “timbre”). Both are characterized by the two physical correlates of timbre: spectrum envelope (i.e., differences in the relative amplitudes of the individual harmonics) and amplitude envelope (also sometimes called the amplitude contour or energy contour of the sound wave, i.e., the way that the loudness of a sound changes, particularly with regard to the onset and offset of a sound). Aperiodic sounds can also differ in spectrum envelope (see, e.g.,

the difference between /f/ and /s/), and timbre differences related to amplitude envelope play a role in speech, e.g., in the shape of the attack for /b/ vs. /w/ and /f/ vs. /t/.

Auditory Feature Extraction in the Auditory Cortex
As mentioned above, auditory information is projected mainly via the subdivisions of the medial geniculate body into the primary auditory cortex (PAC, corresponding to Brodmann's area 41) and adjacent secondary auditory fields (corresponding to Brodmann's areas 42 and 52). These auditory areas perform that a more fine-grained, and more specific, analysis of acoustic features compared to the auditory brainstem. For example, Tramo et al. (2002) reported that a patient with bilateral lesion of the PAC (a) had normal detection thresholds for sounds (i.e., the patient could say whether there was a tone or not), but (b) had elevated thresholds for determining whether two tones had the same pitch or not (i.e., the patient had difficulties to detect fine-grained frequency differences between two subsequent tones) and (c) had markedly increased thresholds for determining the pitch direction (i.e., the patient had great difficulties in saying whether the second tone was higher or lower in pitch than the first tone, *even though* he could tell that both tones differed). Note that the auditory cortex is also involved in a number of other functions, such as auditory sensory memory, extraction of inter-sound relationships, discrimination and organization of sounds as well as sound patterns, stream segregation, automatic change detection, and multisensory integration (Hackett and Kaas 2004; Winkler 2007).

Moreover, the (primary) auditory cortex is involved in the transformation of acoustic features (such as frequency information) into percepts (such as pitch height and pitch chroma): Lesions of the (right) PAC result in a loss of the ability to perceive residue pitch in both animals (Whitfield 1980) and humans (Zatorre 1988), and neurons in the anterolateral region of the PAC show responses to a missing fundamental frequency (Bendor and Wang 2005). Moreover, magnetoencephalographic data indicate that response properties in the PAC depend on whether or not a missing fundamental of a complex tone is

perceived (Patel and Balaban 2001). Note, however, that combination tones emerge already in the cochlea and that the periodicity of complex tones is coded in the spike pattern of auditory brainstem neurons; therefore, different mechanisms contribute to the perception of residue pitch on at least three different levels (basilar membrane, brainstem, and auditory cortex). However, the studies by Zatorre (1988) and Whitfield (1980) suggest that, compared to the brainstem or the basilar membrane, the auditory cortex plays the more prominent role for the transformation of acoustic features into auditory percepts (such as the transformation of information about the frequencies of a complex sound, as well as about the periodicity of a sound, into a pitch percept).

Warren et al. (2003) report that changes in pitch chroma involve auditory regions anterior of the PAC (covering parts of the planum polare) more strongly than changes in pitch height. Conversely, changes in pitch height appear to involve auditory regions posterior of the PAC (covering parts of the planum temporale) more strongly than changes in pitch chroma (Warren et al. 2003). Moreover, with regard to functional differences between the left and the right PAC, as well as neighboring auditory association cortex, several studies suggest that the left auditory cortex (AC) has a higher resolution of temporal information than the right AC and that the right AC has a higher spectral resolution than the left AC (Zatorre et al. 2002; Hyde et al. 2008; Perani et al. 2010).

Finally, the auditory cortex also prepares acoustic information for further conceptual and conscious processing. For example, with regard to the meaning of sounds, just a short single tone can sound, for example, "bright," "rough," or "dull." That is, single tones are already capable of conveying meaning information (this is indicated by the line connecting the module "Feature Extraction II" and "Meaning" in Fig. 1; processing of musical meaning will be dealt with further below).

Operations within the (primary and adjacent) auditory cortex related to auditory feature analysis are reflected in electrophysiological recordings in ERP components that have latencies of about

Music Processing in the Brain, Fig. 1 Neurocognitive model of music perception. mid-latency component, *MMN* mismatch negativity, *RATN* right anterior temporal *ABR* auditory brainstem response, *B4* Brodmann's area, *ERAN* early right anterior negativity, *RCZ* rostral cingulate zone, *SMA* supplementary motor area. *MLC* indicates peak latencies of scalp-recorded evoked potentials

10–100 ms, particularly middle-latency responses, including the P1, and the later “exogenous” N1 component (Pantev et al. 2001).

Echoic Memory and Gestalt Formation

While auditory features are extracted, the acoustic information enters the auditory sensory memory (or “echoic memory”), and representations of auditory Gestalten (Griffiths and Warren 2004) are formed (Fig. 1). Operations of the auditory sensory memory are at least partly reflected electrically in the mismatch negativity (Näätänen et al. 2001). The MMN has a peak latency of about 100–200 ms and most presumably receives its main contributions from neural sources located in the PAC and adjacent auditory (belt) fields, with additional (but smaller) contributions from the frontal cortical areas (for a review see Deouell 2007). These frontal areas appear to include (ventral) the premotor cortex (Brodmann’s area [BA] 6), the dorsolateral prefrontal cortex near and within the inferior frontal sulcus, and the posterior part of the inferior frontal gyrus (BAs 45 and 44). The frontal areas are possibly involved due to their role in attentional processes, sequencing, and working memory processes (Schonwiesner et al. 2007). Auditory sensory memory operations are indispensable for music perception; therefore, practically all MMN studies are inherently related to, and relevant for, the understanding of the neural correlates of music processing. As will be outlined below, numerous MMN studies have contributed to this issue (a) by investigating different response properties of the auditory sensory memory to musical and speech stimuli, (b) by using melodic and rhythmic patterns to investigate auditory Gestalt formation, and/or (c) by studying effects of long- and short-term musical training on processes underlying auditory sensory memory operations. Especially the latter studies have contributed substantially to our understanding of neuroplasticity and thus to our understanding of the neural basis of learning (for reviews, see Tervaniemi and Huotilainen 2003; Tervaniemi 2009). For example, MMN studies showed effects of long-term musical

training on the pitch discrimination of chords (Koelsch et al. 1999), on temporal acuity (Rammsayer and Altenmüller 2006), on the temporal window of integration (Rüsseler et al. 2001), on sound localization changes (Tervaniemi et al. 2006a), and on the detection of spatially peripheral sounds (Rüsseler et al. 2001). Moreover, using MEG, an MMN study from Menning et al. (2000) showed effects of a 3-week auditory musical training on the pitch discrimination of tones.

Auditory oddball paradigms were also used to investigate processes of melodic and rhythmic grouping of tones occurring in tone patterns (Sussman 2007), as well as effects of musical long-term training on these processes. These studies showed effects of musical training (a) on the processing of melodic patterns (e.g., Zuijen et al. 2004), (b) on the encoding of the number of elements in a tone pattern (Zuijen et al. 2005), and (c) on the processing of patterns consisting of two voices (Fujioka et al. 2005).

Finally, several MMN studies investigated differences between the processing of musical and speech information. These studies report larger right-hemispheric responses to chord deviants than to phoneme deviants (e.g., Tervaniemi et al. 2000); similar results have also been shown for the processing of complex tones compared to phonemes (e.g., Tervaniemi et al. 2009). These lateralization effects are presumably due to the different requirements of spectral and temporal processing posed by the chords and the phonemes used as stimuli in that study.

The formation of auditory Gestalten entails processes of perceptual separation, as well as processes of melodic, rhythmic, timbral, and spatial grouping. Such processes have been summarized under the concepts of *auditory scene analysis* and *auditory stream segregation* (Bregman 1994). Grouping of acoustic events follows Gestalt principles such as similarity, proximity, and continuity (e.g., Darwin 2008). In everyday life, such operations are important not only for music processing, but also, for instance, for separating a speaker’s voice during a conversation from other sound sources in the environment. That is, these operations are important because their function is to recognize and to

follow acoustic objects and to establish a cognitive representation of the acoustic environment. Knowledge about neural mechanisms of auditory stream segregation, auditory scene analysis, and auditory grouping is still relatively sparse (e.g., Shinn-Cunningham 2008; Winkler et al. 2009). However, it appears that the planum temporale (which is part of the auditory association cortex) is a crucial structure for auditory scene analysis and stream segregation (Griffiths and Warren 2002), particularly due to its role for the processing of pitch intervals and sound sequences (e.g., Patterson et al. 2002).

Analysis of Intervals

Presumably closely linked to the stage of auditory Gestalt formation is a stage of a more fine-grained analysis of intervals, which includes (i) a more detailed processing of the pitch relations between the tones of a chord (required to determine whether a chord with a specific root is a major or minor chord, played in root position, inversion, etc.; see also below) or between the tones of a melody and possibly (ii) a more detailed processing of temporal intervals. With regard to chords, such an analysis is required to specify the “chord form,” that is, whether a chord is a major or a minor chord and whether a chord is played in root position or in an inversion; note that chords with the same root can occur in several versions (e.g., all of the following chords have the root c: c–e–g, c–e-flat–g, e–g–c, g–c–e, c–e–g–b-flat, e–g–b-flat–c, etc.). The neural correlates of such processes are not known, but it is likely that both temporal and (inferior) prefrontal regions contribute to such processing; with regard to the processing of melodies, lesion data suggest that the analysis of the contour of a melody (which is part of the auditory Gestalt formation) particularly relies on the posterior part of the right superior temporal gyrus (STG), whereas the processing of more detailed interval information appears to involve both posterior and anterior areas of the supratemporal cortex bilaterally (Peretz and Zatorre 2005; Liegeois-Chauvel et al. 1998; Patterson et al. 2002).

Melodic and temporal intervals appear to be processed independently, as suggested by the observation that brain damage can interfere with the discrimination of pitch relations but spare the accurate interpretation of time relations, and vice versa (Peretz and Zatorre 2005; Di Pietro et al. 2004). However, these different types of interval processing have so far not been dissociated in functional neuroimaging studies.

When Intelligence Comes into Play: Processing Musical Syntax

The following section deals with the processing of major–minor tonal syntax, particularly with regard to chord functions (i.e., with regard to harmony; for explanation of chord functions see Fig. 2a). Other aspects of tonal syntax are rhythm, meter, melody (including voice leading), and timbre (including intensity, instrumentation, and texture).

Formal Descriptions of Musical Syntax

Before describing neural correlates of music-syntactic processing, a theoretical basis of musical syntax will be outlined briefly. One possible theoretical description of the syntax of major–minor tonal music is the classical theory of harmony as formulated, e.g., by Jean-Philippe Rameau, Hugo Riemann, Arnold Schönberg, and Walter Piston. These descriptions primarily deal with the derivation of chord functions, less so with how chord functions are chained into longer sequences. Also, these approaches are best suited to describe local dependencies between harmonies.

Heinrich Schenker was the first theorist to deal systematically with the principles underlying non-local dependencies; this included his thoughts on the *Ursatz*, which implicitly assumes (a) a hierarchical structure (such as the large-scale tonic–dominant–tonic structure of the sonata form), (b) that (only) certain chord functions can be omitted, and (c) recursion (e.g., a sequence in one key which is embedded in another sequence in a different key, which is embedded in yet another sequence with yet another different key, etc.). Schenker’s thoughts were formalized by the

Music Processing in the Brain, Fig. 2 (a) Examples of chord functions: The chord built on the first scale tone is denoted as the tonic, the chord on the second tone as the supertonic, and the chord on the fifth tone as the dominant. (b) The dominant-tonic progression represents a regular ending of a harmonic sequence (*top*) and the dominant-tonic progression is less regular and unacceptable as a marker of the end of a harmonic progression (*bottom* sequence, the *arrow* indicates the less regular chord). (c) ERPs elicited in a passive listening condition by the final chords of the two sequence types shown in (b). Both sequence types were presented in pseudorandom order equiprobably in all 12 major keys. Brain responses to irregular chords clearly differ from those to regular chords (best to be seen in the black difference wave, regular

subtracted from irregular chords). The first difference between the two waveforms is maximal around 200 ms after the onset of the fifth chord (ERAN, indicated by the *long arrow*) and taken to reflect processes of music-syntactic analysis. The ERAN is followed by an N5 taken to reflect processes of harmonic integration (*short arrow*). (d) Activation foci (*small spheres*) reported by functional imaging studies on music-syntactic processing using chord sequence paradigms (Koelsch et al. 2002, 2005a; Maess et al. 2001; Tillmann et al. 2003) and melodies (Janata et al. 2002a). *Large yellow spheres* show the mean coordinates of foci (averaged for each hemisphere across studies, coordinates refer to standard stereotaxic space) (Reprinted from Koelsch and Siebel 2005)

approaches of the “Generative Theory of Tonal Music”(GTTM) by Lerdahl and Jackendoff (1999), which, however, does not provide generative rules (in contrast to what its name says). Nevertheless, the advance of the GTTM lies in the description of Schenker’s *Urlinie* as a tree structure (in this regard, GTTM uses terms such as *time-span reduction* and *prolongation*). These tree structures also parallel the description of linguistic syntax using tree structures (Patel (2008)), although Lerdahl and Jackendoff’s GTTM at least implicitly implies that musical and linguistic syntax have only little to do with each other (except perhaps with regard to certain prosodic aspects).

Up to now, only one neurophysiological investigation has tested whether individuals perceive music cognitively according to tree structures (Koelsch et al. 2013), and behavioral studies on this topic are also extremely scarce (Cook 1987; Bigand et al. 1996; Lerdahl and Krumhansl 2007). Note that GTTM is an analytical (not a generative)

model; Lerdahl’s Tonal Pitch Space theory (Lerdahl 2001) attempts to provide algorithms for this analytical approach (but the algorithms are often not sharp and precise). However, TPS provides the very interesting approach to model tension–resolution patterns from tree structures (Lerdahl and Krumhansl 2007).

A more recent approach to model tonal harmony with explicit generative rules according to tree structures is the *Generative Syntax Model* (GSM) by Martin Rohrmeier (2007, 2011). Rohrmeier’s GSM distinguishes between four structural levels with increasing abstraction: a level with the surface structure (in terms of the naming of the chords, e.g., C, G, C), a scale-degree structure level (e.g., I, V, I), a functional–structural level (e.g., t, d, t), and a phrase-structure level specifying tonic regions, dominant regions, and subdominant regions (see also Fig. 3). Each of these levels is described with generative rules of a phrase-structure grammar, the generation beginning on the highest (phrase-structure) level and

Music Processing in the Brain, Fig. 3 Tree structures (according to the GSM) for the sequences shown in Fig. 2b, ending on a regular tonic (*left*) and on a supertonic (*right*). Dashed line, expected structure (≠: the tonic chord is expected, but a supertonic is presented); dotted lines, a possible solution for the integration of the supertonic. TR (→DR) indicates that the supertonic can still be integrated,

e.g., if the expected tonic region is restructured into the dominant region. TR tonic region, DR dominant region, SR subdominant region. Lowercase letters indicate chord functions (functional–structural level), Roman numerals indicate the scale-degree structure, and the *bottom row* indicates the surface structure in terms of the naming of the chords

propagating information (in the process of derivation) through the subordinate levels. This opens the possibility for the recursive derivation of complex sequences on both a functional and a scale-degree structural level (e.g., “dominant of the dominant of the dominant”). The actual tonality of a tree is propagated from the head (“knot”) into the subordinate branches. The tree structure reflects (a) the formal arrangement of the piece, (b) the phrase structure, (c) the functional aspects of partial phrases and chords, (d) the relation of key regions, and (e) the degree of relative stability (which is determined by the subordination rules between the branches).

The GSM combines three principles:

1. Given (a) that musical elements (e.g., a tone or a chord) always occur in relation to other musical elements (and not alone) and (b) that each element (or each group of elements) has a functional relation either to a preceding or to a subsequent element, the simplest way of representing these relations is a tree structure. This implies that relations of elements that are functionally related, but not adjacent, can be represented by a tree structure. For example, in a sequence which consists of several chords and which begins and ends on a tonic chord, the first and the last tonic are not adjacent (because there are other chord functions between them), but the last tonic picks up (and “prolongates”) the first tonic; this can be represented in a tree structure in a way that the first and the last tonic chords build beginning points and endpoints of the tree and that the relations of the other chord functions can be represented by dendritic ramification (“prolongating” chords can extend the tonal region and “progressing” chords determine the progression of tonal functions). This also implies that adjacent elements do not necessarily have a direct structural relation (e.g., an initial tonic chord can be followed by a secondary dominant to the next chord; the secondary dominant then has a direct relation to the next chord, but not to the preceding tonic chord). It is not possible that a chord does not have a functional relation to a preceding nor to a subsequent
2. The tree structure indicates which elements can successively be omitted in a way that the sequence still sounds correct. For example, secondary dominants can be omitted or all chords between first and last tonic chord can be omitted, and a sequence still sounds correct. In a less trivial case, there is a dominant in a local phrase between two tonic chords; the tree structure then indicates that on the next higher level, all chords except the two tonic and the dominant chords can be omitted. This principle is a consequence of the “headedness,” in which each knot in the syntax tree dominates subordinate branches. That is, the tree structure provides a weighting of the elements, leading to an objectively derivable deep structure (another advantage compared to the classical theory of harmony).
3. Chord functions are a result of their position within the branches of the tree. For example, a predominant is the subordinate branch preceding a dominant, or there are stable and instable dominants which can be differentiated based on how deeply they are located in the syntax tree. Similarly, a half-cadence is a case in which a dominant is reached as stable local endpoint of a phrase, which must be followed by a phrase that ends on a tonic, thus resolving the open dominant (with regard to the deep structure).

As mentioned before, the GSM is relatively new, and due to the lack of usable tree models, most studies investigating neurophysiological correlates of music-syntactic processing have so far simply utilized the classical theory of harmony as a syntactic rule system (for an exception see Koelsch et al. 2013): According to the classical

theory of harmony, chord functions are arranged within harmonic sequences according to certain regularities (Riemann 1877/1971). Ity-based arrangement implies long-distance dependencies involving hierarchical organization (also referred to as phrase-structure grammar). However, it cannot be excluded that “irregular” chord functions such as the final supertonic in Fig. 2b are detected as irregular based on a finite state grammar (according to which the tonic is the most regular chord after a I–IV–II–V progression); as will be illustrated below, processing of such chord functions presumably involves processing of both finite state and phrase-structure grammar.

Neural Correlates of Music-Syntactic Processing

Neurophysiological studies using EEG and MEG showed that music-syntactically irregular chord functions (such as the final supertonic shown in Fig. 2b) elicit brain potentials with negative polarity that are maximal at around 150–350 ms after the onset of an irregular chord and have a frontal/frontotemporal scalp distribution, often with right-hemispheric weighting (see also Fig. 2c). In experiments with isochronous, repetitive stimulation, this effect is maximal at around 150–200 ms over right anterior electrodes and denoted as early right anterior negativity or ERAN (Koelsch 2009a). In experiments in which the position of irregular chords within a sequence is not known (and thus unpredictable), the negativity often has a longer latency and a more anterior–temporal distribution (Patel et al. 1998; Koelsch and Mulder 2002). The ERAN elicited by irregular tones of melodies has a shorter peak latency than the ERAN elicited by irregular chord functions (Koelsch and Jentschke 2010).

Functional neuroimaging studies using chord sequence paradigms or melodies suggest that music-syntactic processing involves the pars opercularis of the inferior frontal gyrus (corresponding to BA 44) bilaterally, but with right-hemispheric weighting (see yellow spheres in Fig. 2d). It seems likely that the involvement of (inferior) BA 44 in music-syntactic processing is due to the hierarchical processing of (syntactic)

information: This part of Broca’s area is involved in the hierarchical processing of syntax in language (Friederici et al. 2006; Makuuchi et al. 2009), in the hierarchical processing of action sequences (Koechlin and Jubault 2006; Fazio et al. 2009), and possibly also in the processing of hierarchically organized mathematical formulas and termini (Friedrich and Friederici 2009). These findings suggest that at least some cognitive operations of music-syntactic and language-syntactic processing (and neural populations mediating such operations) overlap and are shared with the syntactic processing of actions, mathematical formulas, and other structures based on long-distance dependencies involving hierarchical organization (phrase-structure grammar).

However, it appears that inferior BA 44 is not the only structure involved in music-syntactic processing: Additional structures include the superior part of the pars opercularis (Koelsch et al. 2002), the anterior portion of the STG (Koelsch et al. 2002, 2005a), and ventral premotor cortex (Janata et al. 2002a, b; Koelsch et al. 2002, 2005a; Parsons 2001). The PMCV probably contributes to the processing of music-syntactic information based on finite state grammar: Activations of PMCV have been reported in a variety of functional imaging studies on auditory processing using musical stimuli, linguistic stimuli, auditory oddball paradigms, pitch discrimination tasks, and serial prediction tasks, underlining the importance of these structures for the sequencing of structural information, the recognition of structure, and the prediction of sequential information (Janata and Grafton 2003). With regard to language, Friederici (2004) reported that activation foci of functional neuroimaging studies on the processing of long-distance hierarchies and transformations are located in the posterior IFG (in the inferior pars opercularis), whereas activation foci of functional neuroimaging studies on the processing of local structural violations are located in the PMCV (Friederici et al. 2006; Makuuchi et al. 2009; Opitz and Kotz 2012). Moreover, patients with lesion in the PMCV show disruption of the processing of finite state, but not phrase-structure grammar (Opitz and Kotz 2012).

That is, in the abovementioned experiments that used chord sequence paradigms to investigate the processing of harmonic structure, the music-syntactic processing of the chord functions probably involved processing of both finite state and phrase-structure grammar. The music-syntactic analysis involved a computation of the harmonic relation between a chord function and the context of preceding chord functions (phrase-structure grammar). Such a computation is more difficult (and less common) for irregular than for regular chord functions (as illustrated by the branch with the dashed line in the right panel of Fig. 3), and this increased difficulty is presumably reflected in a stronger activation of (inferior) BA 44 in response to irregular chords. In addition, the local transition probability from the penultimate to the final chord is lower for the dominant–super-tonic progression than for the dominant–tonic progression (finite state grammar), and the computation of the (less predicted) lower-probability progression is presumably reflected in a stronger activation of PMCV in response to irregular chords. The stronger activation of both BA 44 and PMCV appears to correlate with the perception of a music-syntactically irregular chord as “unexpected.”

Note that the ability to process phrase-structure grammar is available to humans, whereas non-human primates are apparently not able to master such grammars (Fitch and Hauser 2004). Thus, it is highly likely that only humans can adequately process music-syntactic information at the phrase-structure level. It is also worth noting that numerous studies showed that even “nonmusicians” (i.e., individuals who have not received formal musical training) have a highly sophisticated (implicit) knowledge about musical syntax (Rohrmeier and Rebuschat 2012). Such knowledge is presumably acquired during listening experiences in everyday life.

Interactions Between Language- and Music-Syntactic Processing

As mentioned above, hierarchical processing of syntactic information from different domains (such as music and language) requires contributions from neural populations located in BA 44.

However, it is still possible that, although such neural populations are located in the same brain area, entirely different (nonoverlapping) neural populations serve the syntactic processing of music and language *within the same area*. That is, perhaps the neural populations mediating language-syntactic processing in BA 44 are different from neural populations mediating music-syntactic processing in the same area. Therefore, the strongest evidence for shared neural resources for the syntactic processing of music and language stems from experiments that revealed interactions between music-syntactic and language-syntactic processing (Koelsch et al. 2005b; Steinbeis and Koelsch 2008b; Slevc et al. 2009; Fedorenko et al. 2009). In these studies, chord sequences were presented simultaneously with visually presented sentences (for an example see Fig. 4). Two of these studies (Koelsch et al. 2005b; Steinbeis and Koelsch 2008b) used EEG and three different sentence types. The first type was a syntactically correct sentence in which the occurrence of the final noun was semantically highly probable. The other two sentence types were modified versions of the first sentence type: firstly, a sentence with a gender disagreement between the last word (noun) on the one hand and the prenominal adjective as well as the definite article that preceded the adjective on the other (such gender disagreements elicit a left anterior negativity; Gunter et al. 2000) and, secondly, a sentence in which the final noun was semantically less probable – such “low-cloze probability” words elicit an N400 reflecting the semantic processing of words (see also section on musical semantics below). Each chord sequence consisted of five chords (and each chord was presented together with a word, see Fig. 4), one chord sequence type ending on a music-syntactically regular and the other type ending on an incorrect chord function.

Both studies (Koelsch et al. 2005b; Steinbeis and Koelsch 2008b) showed that the ERAN elicited by irregular chords interacted with the left anterior negativity (LAN) elicited by linguistic (morpho-syntactic) violations (Koelsch et al. 2005b; Steinbeis and Koelsch 2008b): The LAN elicited by words was reduced when the syntactically irregular word was presented simultaneously

Music Processing in the Brain, Fig. 4 Examples of experimental stimuli used in the studies by Koelsch et al. (2005b) and Steinbeis and Koelsch (2008b). *Top*: examples of two chord sequences in C major, ending on a regular (*upper row*) and an irregular chord (*lower row*, the irregular

chord is indicated by the *arrow*). *Bottom*: examples of the three different sentence types. Onsets of chords (presented auditorily) and words (presented visually) were synchronous. (Reprinted from Steinbeis and Koelsch 2008b)

with a music-syntactically irregular chord (compared to when the irregular word was presented with a regular chord). In the study by Koelsch et al. (2005b), a control experiment was conducted in which the same sentences were presented simultaneously with sequences of single tones. The tone sequences ended either on a standard tone or on a frequency deviant. The physical mismatch negativity (phMMN) elicited by the frequency deviants did not interact with the LAN (in contrast to the ERAN), indicating that the processing of auditory oddballs (as reflected in the phMMN) does not consume resources related to syntactic processing. In addition, the study by Steinbeis and Koelsch (2008b) also showed that the amplitude of the ERAN was reduced when

participants processed a syntactically wrong word (Fig. 5a). Notably, the ERAN was not affected when words were semantically incongruous (Fig. 5b), showing that the interaction between ERAN and LAN is specific for syntactic processing.

The findings of these EEG studies were corroborated by two behavioral studies (Slevc et al. 2009; Fedorenko et al. 2009), as well as by a patient study by Patel et al. (2008). The latter study showed that individuals with Broca's aphasia also show impaired music-syntactic processing in response to out-of-key chords occurring in harmonic progressions (note that all patients had Broca's aphasia, but only some of them had a lesion that included Broca's area).

Music Processing in the Brain, Fig. 5 Grand-average ERPs elicited by the stimuli shown in Fig. 4. Participants monitored whether the sentences were (syntactically and semantically) correct or incorrect; in addition, they had to attend to the timbre of the chord sequences and to detect infrequently occurring timbre deviants. ERPs were recorded on the final chords/words and are shown for the different word conditions (note that only difference waves are shown). (a) The solid (blue) difference wave shows ERAN (indicated by the arrow) and N5 elicited on syntactically and semantically correct words. The dashed (green) difference wave shows ERAN and N5, elicited when chords are presented on morpho-syntactically incorrect (but semantically correct) words. Under the latter condition, the ERAN (but not the N5) is reduced. (b) The solid (blue) difference wave is identical to the solid difference

wave of (a), showing the ERAN and the N5 (indicated by the arrow) elicited on syntactically and semantically correct words. The dotted (red) difference wave shows ERAN and N5, elicited when chords are presented on semantically incorrect (but morpho-syntactically correct words). Under the latter condition, the N5 (but not the ERAN) is reduced. (c) shows the direct comparison of the difference waves in which words were syntactically incorrect (dashed, green line) or semantically incorrect (dotted, red line). These ERPs show that the ERAN is influenced by the morpho-syntactic processing of words, but not by the semantic processing of words. By contrast, the N5 is influenced by the semantic processing of words, but not by the morpho-syntactic processing of words. (Data from Steinbeis and Koelsch 2008b)

It is also interesting to note that there are hints for an interaction between the ERAN and the *early left anterior negativity* (Friederici 2002): In a study by Maidhof and Koelsch (2011), participants were presented simultaneously with spoken sentences and chord sequences. Thus, the experiment was similar to the studies by Koelsch et al. (2005b) and Steinbeis and Koelsch (2008b), except (a) that sentences were presented auditorily, (b) that syntactic violations were phrase-structure violations (not morpho-syntactic violations), and (c) that the attention of listeners was directed to either the speech or the music. In that study, the amplitude of the ERAN was slightly smaller when elicited during the presentation of phrase-structure violations occurring in sentences

(compared to when elicited during correct sentences); this effect was, however, only marginally significant. Thus, it appears that music-syntactic processing of an irregular chord function (as reflected in the ERAN) also interacts with the processing of the phrase structure of a sentence, although this interaction seems less obvious than the interaction between ERAN and LAN (i.e., between music-syntactic processing of chord functions and the processing of morpho-syntactic information in language).

In summary, neurophysiological studies show that music- and language-syntactic processes engage overlapping resources (presumably located in the inferior fronto-lateral cortex), and evidence showing that these resources underlie

music- and language-syntactic processing is provided by experiments showing interactions between ERP components reflecting music- and language-syntactic processing (in particular LAN and ERAN). Importantly, such interactions are observed in the absence of interactions between LAN and MMN, i.e., in the absence between language-syntactic and acoustic deviance processing (reflected in the MMN) and in the absence of interactions between the ERAN and the N400 (i.e., in the absence of music-syntactic and language-semantic processing). Therefore, the reported interactions between LAN and ERAN are syntax-specific and cannot be observed in response to any kind of irregularity.

Processing of Phrase Boundaries

During auditory music or language perception, the recognition of phrase boundaries helps to decode the syntactic (phrase) structure of a musical phrase, as well as of a sentence (the melodic and rhythmic features that mark a phrase boundary in a spoken sentence are part of the *speech prosody*). The processing of phrase boundaries is reflected in a *Closure Positive Shift* (CPS), during both the processing of musical phrase boundaries (Knösche et al. 2005) and the processing of international phrase boundaries during speech perception (Steinhauer et al. 1999). The first study on the perception of musical phrase boundaries by Knösche et al. (2005) investigated musicians only, and a subsequent study also reported a CPS in nonmusicians (Neuhaus et al. 2006). The latter study also reported larger CPS amplitudes for longer pauses as well as longer boundary tones (which make the phrase boundary more salient). Both studies (Knösche et al. 2005; Neuhaus et al. 2006) used EEG as well as MEG, showing that the CPS can be observed with both methods. In a third study, Chinese and German musicians performed a categorization task with Chinese and Western music (Nan et al. 2006). Both groups showed CPS responses to both types of music (with no significant difference between groups). The exact contributions of the processes reflected in the CPS to syntactic processing remain to be specified.

Using fMRI, a study by Meyer et al. (2004) suggests that the processing of the prosodic

aspects of the sentences used in the study by Steinhauer et al. (1999) involves the premotor cortex of the (right) Rolandic operculum, (right) the auditory cortex located in the planum temporale, as well as the anterior insula (or perhaps deep frontal operculum) and the striatum bilaterally.

A very similar activation pattern was also observed for the processing of the melodic contour of spoken main clauses (Meyer et al. 2002). That is, similar to the right-hemispheric weighting of activations observed in functional neuroimaging studies on music perception, a right-hemispheric weighting of (neocortical) activations is also observed for the processing of speech melody.

Structural Reanalysis and Repair

Following a syntactic anomaly (or an unexpected syntactic structure), processes of structural reanalysis and repair may be engaged. It appears that these processes are reflected in the ERP as positive potentials that are maximal around 600–900 ms (Besson and Schön 2001).

The P600/LPC can be elicited by irregular melody tones (Besson and Macar 1986; Besson and Faita 1995; Verleger 1990; Paller et al. 1992; Besson and Faita 1995; Besson et al. 1998; Miranda and Ullman 2007; Peretz et al. 2009), as well as by irregular chords (Patel et al. 1998). It seems that the P600/LPC can only be elicited when individuals attend to the musical stimulus and that the LPC is partly connected to processes of the conscious detection of music-structural incongruities. In an experiment by Besson and Faita (1995), in which incongruous melody endings had to be detected, the LPCs had a greater amplitude, and a shorter latency, in musicians compared to “nonmusicians,” presumably because musicians were more familiar with the melodies than nonmusicians (thus, musicians could detect the irregular events more easily). Moreover, the LPC had a larger amplitude for familiar melodies than for novel melodies (presumably because incongruous endings of familiar phrases were easier to detect) and for

non-diatonic than for diatonic endings. Diatonic incongruities terminating unfamiliar melodies did not elicit an LPC (presumably because they are hardly to detect), whereas non-diatonic incongruities did (they were detectable for participants by the application of tonal rules).

It is remarkable that in *all* of the mentioned studies on melodies (Besson and Macar 1986; Verleger 1990; Paller et al. 1992; Besson and Faita 1995; Besson et al. 1998; Miranda and Ullman 2007; Brattico et al. 2006; Peretz et al. 2009), the unexpected tones also elicited an early frontal negative ERP (emerging around the N1 peak, i.e., around 100 ms after stimulus onset). This ERP effect resembles the ERAN (Koelsch and Jentschke 2010), although it presumably overlapped in part with a subsequent N2b due to the detection of irregular or unexpected tones. That is, earlier processes underlying the detection of structural irregularities (as partly reflected in the ERAN) are followed by later processes of structural reanalysis (as reflected in the P600/LPC) when individuals attend to the musical stimulus and detect structural incongruities. It remains to be specified whether the P600/LPC is a late P3 and how the processes of structural reanalysis and repair are possibly related to context-updating (Donchin and Coles 1998; Polich 2007).

Using sentences and chord sequences, Patel et al. (1998) compared ERPs elicited by “syntactic incongruities” in language and music within subjects (harmonic incongruities were taken as grammatical incongruity in music). Task-relevant (target) chords within homophonic musical phrases were manipulated, so that the targets were either within the key of a phrase or out of key (from a “nearby” or a “distant” key). Both musical and linguistic structural incongruities elicited P600/LPC potentials which were maximal at posterior sites and statistically indistinguishable. Moreover, the degree of a structural anomaly (moderate or high) was reflected in the amplitude of the elicited positivities. Therefore, the results indicated that the P600 reflects more general knowledge-based structural (re-)integration (and/or reanalysis) during the perception of rule-governed sequences. The intersection between the processes of music-syntactic and language-

syntactic (re)integration and repair is referred to as the *Shared Syntactic Integration Resource Hypothesis* (SSIRH), which states that music and language rely on shared, limited processing resources that activate separable syntactic representations (Patel 2003). The SSIRH also states that whereas the linguistic and musical knowledge systems may be independent, the system used for online structural integration may be shared between language and music (Fedorenko et al. 2009). This system might be involved in the integration of incoming elements (words in language and tones/chords in music) into evolving structures (sentences in language, harmonic sequences in music). Beyond the SSIRH, however, the previous section on music-syntactic processing also showed early interactions (between the ERAN and LAN), indicating that processing of music- and language-syntactic information intersects also at levels of morpho-syntactic processing, phrase-structure processing, and possibly word-category information. The overlap of cognitive resources (and their neural correlates) for the early and late processing of syntactic information in music, language, actions, mathematical formulas, etc. has been referred to as the *Syntactic Equivalence Hypothesis* (Koelsch 2012).

Processing Meaning in Music

Music is a means of communication, and during music listening, meaning emerges through the interpretation of (musical) information. Previous accounts on musical meaning can be summarized with regard to three fundamentally different classes of meaning emerging from musical information: extramusical meaning, intra-musical meaning, and musicogenic meaning (Koelsch 2011). Extramusical meaning refers to meaning emerging from reference to the extramusical world (Meyer 1956). This class of meaning comprises three dimensions: musical meaning due to iconic, indexical, and symbolic sign qualities (Karbusicky 1986).

- (a) Iconic musical meaning emerges from common patterns or forms, such as musical sound

patterns that resemble sounds of objects or qualities of objects. For example, acoustic events may sound “warm,” “round,” “sharp,” or “colorful,” and a musical passage may sound, e.g., “like a bird” or “like a thunderstorm.” In linguistics, this sign quality is also referred to as *onomatopoeic*.

- (b) Indexical musical meaning emerges from action-related patterns (such as movements and prosody) that index the presence of a psychological state, for example, an emotion or an intention. Juslin and Laukka (2003) compared in a meta-analysis the acoustical signs of emotional expression in music and speech, finding that the acoustic properties that code emotional expression in speech are highly similar to those coding these expressions in music. With regard to intentions, an fMRI study by Steinbeis and Koelsch (2008c) showed that listeners automatically engage social cognition during listening to music, in an attempt to decode the intentions of the composer or performer (as indicated by activations of the cortical *theory-of-mind* network). That study also reported activations of posterior temporal regions implicated in semantic processing (Lau et al. 2008), presumably because the decoding of intentions has meaning quality. Ian Cross (2008) refers to this dimension of musical meaning as “motivational–structural” due to the relationship between affective–motivational states of individuals on the one side and the structural–acoustical characteristics of (species-specific) vocalizations on the other.
- (c) Symbolic musical meaning emerges from explicit (or conventional) extramusical associations (e.g., any national anthem). Note that the meaning of the majority of words is due to symbolic meaning. Cross and Morley (2008) refers to this dimension of musical meaning as “culturally enactive,” emphasizing that symbolic qualities of musical practice are shaped by (and shape) culture.

Musical semantics, notably, extends beyond the relations between concepts and the (extramusical) world in that musical meaning

also emerges from the reference of one musical element to another musical element, that is, from intra-musical combinations of formal structures. The term “intra-musical” was also used by Malcolm Budd (1996); other theorists have used the terms “formal meaning” (Alpersen 1994), “formal significance” (Davies 1994), or “embodied meaning” (Meyer 1956). Similar distinctions as the one drawn here between extra- and intra-musical meaning have been made by several theorists (Koopman and Davies 2001).

Processing of musical meaning information is reflected in (at least) two negative ERP components: the N400 and the N5. The N400 reflects processing of meaning in both language and music; the N5 has so far only been observed for the processing of musical information. In the following I will present evidence showing that, with regard to the processing of musical meaning, the N400 reflects processing of extramusical meaning and the N5 processing of intra-musical meaning.

The N400 has been used to investigate processing of musical meaning (or “musical semantics”) in semantic priming paradigms (Koelsch et al. 2004; Steinbeis and Koelsch 2008a; Daltrozzo and Schön 2009a; Steinbeis and Koelsch 2011; Grieser-Painter and Koelsch 2011). In an initial study (Koelsch et al. 2004), sentences and musical excerpts were presented as prime stimuli. The prime stimuli were semantically either related or unrelated to a target word that followed the prime stimulus (see top of Fig. 6). For example, the sentence “The gaze wandered into the distance” primes the word “wideness” (semantically related), rather than the word “narrowness” (semantically unrelated). Analogously, certain musical passages, for example, from a symphony by Mozart, prime the word “angel,” rather than the word “scallywag.”

In the language condition (i.e., when target words followed the presentation of sentences), unrelated words elicited a clear N400 effect (this is a classical semantic priming effect). This semantic priming effect was also observed when target words followed musical excerpts. That is, target words that were semantically unrelated to a preceding musical excerpt also elicited a clear

Music Processing in the Brain, Fig. 6 Left: examples of the four experimental conditions preceding a visually presented target word. *Top panel:* prime sentence semantically related to (a) and unrelated to (b) the target word *wideness*. The diagram on the right shows grand-average ERPs elicited by target words after the presentation of semantically related (solid line) and unrelated prime sentences (dotted line), recorded from a central electrode. Unprimed target words elicited a clear N400 component in the ERP (compared to the primed target words). *Bottom panel:* musical semantically related to (c) and unrelated to (d) the same target word. The diagram on the right shows

grand-average ERPs elicited by target words after the presentation of semantically related (solid line) and unrelated prime sentence (dotted line). As after the presentation of sentences, unprimed target words elicited a clear N400 component (compared to primed target words). Each trial was presented once; conditions were distributed in random order, but counterbalanced across the experiment. Note that the same target word was used for the four different conditions. Thus, condition-dependent ERP effects elicited by the target words can only be due to the different preceding contexts. (Reprinted from Koelsch et al. 2004)

N400. The N400 effects did not differ between the language condition (in which the target words followed sentences) and the music condition (in which the target words followed musical excerpts), neither with respect to amplitude nor with respect to latency or scalp distribution. A source analysis localized the main sources of the N400 effects, in both conditions, in the posterior part of the medial temporal gyrus bilaterally (BA 21/37), in proximity to the superior temporal sulcus. These regions have been implicated in the processing of semantic information during language processing (Lau et al. 2008).

The N400 effect in the music condition demonstrates that musical information can have a systematic influence on the semantic processing of words. The N400 effects did not differ between the music and the language condition, indicating that musical and linguistic priming can have the same effects on the semantic processing of words. That is, the data demonstrated that music can activate representations of meaningful concepts (and that, thus, music is capable of transferring considerably more meaningful information than previously believed) and that the cognitive operations that decode meaningful information while

listening to music can be identical to those that serve semantic processing during language perception. The N400 effect was observed for both abstract and concrete words, showing that music can convey both abstract and concrete semantic information. Moreover, effects were also observed when emotional relationships between prime and target words were balanced, indicating that music does not only transfer emotional information.

The priming of meaning by the musical information was due to (a) iconic sign qualities, i.e., common patterns or forms (such as succeeding interval steps priming the word staircase); (b) indexical sign quality, such as the suggestion of a particular emotion due to the resemblance to movements and prosody typical for that emotion (e.g., saxophone tones sounding like derisive laughter); or (c) symbolic sign quality due to meaning inferred by explicit extramusical associations (e.g., a church anthem priming the word devotion). Unfortunately, it was not investigated in that study whether N400 responses differed between these dimensions of musical meaning (and, so far, no subsequent study has investigated this). However, the results still allow to conclude

that processing of extramusical meaning is associated with N400 effects.

Due to the length of musical excerpts (~10 s), musical information could not be used as target stimulus; thus, only words were used as target stimuli (and the N400 was only elicited on words, not on musical information). Hence, a question emerging from that study was whether musical information can also elicit N400 responses. One study addressing this issue (Daltrozzo and Schön 2009a) used short musical excerpts (duration was ~1 s) that could be used either as primes (in combination with word targets) or as targets (in combination with word primes). Figure 7 shows that when the musical excerpts were used as primes, meaningfully unrelated target words elicited an N400 (Koelsch et al. 2004). Importantly, when musical excerpts were used as target stimuli (and words as primes), an N400 was observed in response to excerpts that the participants rated as meaningfully unrelated to the preceding target word (compared to excerpts that were rated as related to the preceding word). This was the first evidence that musical information can also elicit N400 responses. Note that the musical excerpts were composed for the

Music Processing in the Brain, Fig. 7 Data from the experiments by Daltrozzo and Schön (2009a). The *left* panel shows ERPs elicited by target words (primed by short musical excerpts); the *right* panel shows ERPs elicited by musical excerpts (primed by target words). The thick line represents ERPs elicited by unrelated

stimuli; the *thin* line represents ERPs elicited by related stimuli. Note that the difference in N1 and P2 components is due to the fact that words were presented visually and musical excerpts auditorily. Both meaningfully unrelated words and meaningfully unrelated musical excerpts elicited N400 potentials

experiment and thus not known by the participants. Therefore, musical meaning was not due to symbolic meaning, but due to indexical (e.g., “happy”) and iconic (e.g., “light”) meaning. In the data analysis used in that study (Daltrozzo and Schön 2009a), the relatedness of prime-target pairs was based on the relatedness judgments of participants. Another study (Daltrozzo and Schön 2009b) showed that even if the data are analyzed based on the un-/relatedness of prime-target pairs as predefined by the experimenters, a significant N400 was elicited (in the latter study a lexical decision task was used, whereas in the former study participants were asked to judge the conceptual relatedness of prime and targets). Further studies investigated the processing of musical meaning using only single chords (Steinbeis and Koelsch 2008a; Steinbeis and Koelsch 2011) or single tones (Grieser-Painter and Koelsch 2011). These studies showed that even single chords and tones can prime the meaning of words (in both musicians and nonmusicians) and that even chords (in musicians) and tones (in nonmusicians and therefore presumably also in musicians) can elicit N400 effects.

Intra-musical Meaning and the N5

The previous section dealt with the N400 and extramusical meaning. However, musical meaning can also emerge from intra-musical references, that is, from the reference of one musical element to at least one other musical element (e.g., a *G* major chord is usually perceived as the tonic in *G* major, as the dominant in *C* major, and – in its first inversion – possibly as a Neapolitan sixth chord in *F#* minor). This section will review empirical evidence for this hypothesis and describe an electrophysiological correlate of the processing of intra-musical meaning (the so-called N5, or N500). The N5 was described first in reports of experiments using chord sequence paradigms with music-syntactically regular and irregular chord functions (Koelsch 2000), in which the ERAN was usually followed by a late negativity, the N5 (see also Fig. 2c). Initially (Koelsch 2000) the N5 was proposed to reflect processes of harmonic integration, reminiscent of the N400 reflecting semantic integration of words,

and therefore proposed to be related to the processing of musical meaning, or musical semantics, although the type of musical meaning had remained unclear.

One reason for this proposition was a remarkable resemblance between N5 and N400: *Firstly*, similar to the N400 elicited by open-class words, which declines towards the end of sentences (Van Petten and Kutas 1990), the amplitude of the N5 (elicited by regular chords) declined towards the end of a chord sequence (Koelsch 2000). That is, during sentence processing, a semantically correct final open-class word usually elicits a rather small N400, whereas the open-class words preceding this word elicit larger N400 potentials. This is due to the semantic expectedness of words, which is rather unspecific at the beginning of a sentence, and which becomes more and more specific towards the end of the sentence (where people already have a hunch of what the last word will actually be). Thus, a smaller amount of semantic integration is required at the end of a sentence, reflected in a smaller N400. If the last word is semantically unexpected, then a large amount of semantics is required, which is reflected in a larger amplitude of the N400. Similarly, the N5 is elicited not only by irregular chords but also by regular chords, and the amplitude of the N5 decreases with each progressing chord of the chord sequence. A small N5 elicited by the (expected) final chord of a chord sequence presumably reflects that only a small amount of harmonic integration is required at this position of a chord sequence.

Secondly, at the same position within a chord sequence (or a sentence) the N5 (or the N400) is modulated by the degree of fit with regard to the previous harmonic (or semantic) context. A wealth of studies has shown that irregular chords (Koelsch 2004, 2009a) and irregular tones of melodies (Miranda and Ullman 2007; Koelsch and Jentschke 2010) evoke larger N5 potentials than regular ones (see also Fig. 2c). As mentioned above, the ERAN is related to syntactic processing. In addition, the experiment from Steinbeis and Koelsch 2008b also showed that the N5 reflects processing of meaning information: In that study, the N5 interacted with the N400

elicited by words with low semantic cloze probability. The N5 was smaller when elicited on words that were semantically less probable (“He sees the cold beer”) compared to when elicited on words that were semantically highly probable (“He drinks the cold beer”; see Fig. 5b). Importantly, the N5 did not interact with the LAN (i.e., the N5 did not interact with the syntactic processing of words), indicating that the N5 is not simply modulated by any type of deviance, or incongruency, but that the N5 is specifically modulated by neural mechanisms underlying semantic information processing. That is, the N5 potential can be modulated by semantic processes, namely, by the activation of lexical representations of words with different semantic fit to a previous context. This modulation indicates that the N5 is related to the processing of meaning. Note that the harmonic relation between the chord functions of a harmonic sequence is an intra-musical reference (i.e., a reference of one musical element to another musical element and not a reference to anything belonging to the extramusical world). Therefore, we have reason to believe that the N5 reflects the processing of intra-musical meaning.

The neural generators of the N5 have remained elusive. This is in part due to the difficulty that in most experiments the N5 follows the ERAN (but see also Poulin-Charronnat et al. 2006), making it difficult to differentiate the neural correlates of N5 and ERAN in experiments using functional magnetic resonance imaging. The N5 usually has a clear frontal scalp distribution; thus, the scalp distribution of the N5 is more anterior than that of the N400, suggesting at least partly different neural correlates. Perhaps the N5 originates from combined sources in the temporal lobe (possibly overlapping with those of the N400 in BAs 21/37) and the frontal lobe (possibly in the posterior part of the inferior frontal gyrus). This needs to be specified, for example, using EEG source localization in a study that compares an auditory N4 with an auditory N5 within subjects.

The third class of musical meaning (musicogenic meaning) emerges from individual responses to musical information, particularly movement, emotional responses, and self-related memory associations. This dimension of musical meaning, as well

as details about the extra- and intra-musical dimensions of musical meaning, is discussed in more detail elsewhere (Koelsch 2011).

How the Body Reacts to Music

The present model of music perception also takes the potential “vitalization” of an individual into account: Vitalization entails activity of the autonomic nervous system (i.e., regulation of sympathetic and parasympathetic activity) along with the cognitive integration of musical and non-musical information. Nonmusical information comprises associations evoked by the music, as well as emotional (e.g., happy) and bodily reactions (e.g., tensioned or relaxed). The *subjective feeling* (Scherer 2005) requires conscious awareness and therefore presumably involves multimodal association cortices such as parietal association cortices in the region of BA 7 (Block 2005). Effects of music perception on activity of the autonomic nervous system have mainly been investigated by measuring electrodermal activity and heart rate, as well as the number and intensity of reported “shivers” and “chills” (Khalfa et al. 2002; Blood and Zatorre 2001; Panksepp and Bernatzky 2002; Sloboda 1991; Grewe et al. 2007a, b; Lundqvist et al. 2009; Orini et al. 2010).

Vitalizing processes can, in turn, have an influence on processes within the immune system. Effects of music processing on the immune system have been assessed by measuring variations of (salivary) immunoglobulin A concentrations (Hucklebridge et al. 2000; McCraty et al. 1996; Kreutz et al. 2004). Interestingly, effects on the immune system have been suggested to be tied to motor activity such as singing (Kreutz et al. 2004) or dancing (Quiroga Murcia et al. 2009). With regard to music perception, it is important to note that there might be overlap between neural activities of the late stages of perception and those related to the early stages of action (Rizzolatti and Craighero 2004; Janata et al. 2002b).

Music perception can interfere with action planning in musicians (Drost et al. 2005a, b), and premotor activity can be observed during the perception of music (a) in pianists listening to

piano pieces (Haueisen and Knösche 2001), (b) in nonmusicians listening to song (Callan et al. 2006), and (c) in nonmusicians who received 1 week of piano training and listened to the trained piano melody (Lahav et al. (2007)). For neuroscience studies related to music production, see, e.g., Bangert and Altenmüller (2003), Katahira et al. (2008), Maidhof et al. (2009), Kamiyama et al. (2010), and Maidhof et al. (2010).

Movement induction by music perception in the way of dancing, singing, tapping, hopping, swaying, head-nodding, etc. along with music is a very common experience (Panksepp and Bernatzky 2002); such movements also serve social functions, because synchronized movements of different individuals represent coordinated social activity. Notably, humans have a need to engage in social activities; emotional effects of such engagement include fun, joy, and happiness, whereas exclusion from this engagement represents an emotional stressor and has deleterious effects on health. Humans making music is an activity involving several social functions (summarized as the “Seven Cs”; Koelsch 2014): (1) When we make music, we make *contact* with other individuals (preventing from social isolation). (2) Music automatically engages *social cognition* (Steinbeis and Koelsch 2008c). (3) Music engages *co-pathy* (the social function of empathy) in the sense that interindividual emotional states become more homogenous (e.g., reducing anger in one individual and depression or anxiety in another), thus promoting interindividual understanding and decrease of conflicts. (4) Music involves *communication* (Fitch 2006; Trehub 2003). (5) Music making also involves coordination of movements (Overy and Molnar-Szakacs 2009; Patel et al. 2009; Kirschner and Tomasello 2009). The coordination of movements in a group of individuals appears to be associated with pleasure (e.g., when dancing together), even in the absence of an explicit shared goal (apart from deriving pleasure from concerted movements). (6) Performing music also requires *cooperation* (involving a shared goal and increasing interindividual trust); notably, engaging in cooperative behavior is an

important potential source of pleasure (Rilling et al. 2002). (7) As an effect, music leads to increased *social cohesion* of a group (Cross and Morley 2008), fulfilling the “need to belong” (Baumeister and Leary 1995), and the motivation to form and maintain interpersonal attachments. Social cohesion also strengthens the confidence in reciprocal care (Trehub 2003), and the confidence that opportunities to engage with others in the mentioned social functions will also emerge in the future. Social cohesion has aesthetic quality because it can be experienced as beautiful.

Music seems to be capable of engaging all of the “Seven Cs” at the same time, which can lead to “aesthetic emotions” such as transcendence and spirituality. These evolutionarily advantageous social aspects of music-making behavior represent one origin for the evolution of music-making behavior in humans.

Action induction by music perception is accompanied by neural impulses in the reticular formation (in the brainstem; e.g., for the release of energy to move during joyful excitement). It is highly likely that connections also exist between the reticular formation and structures of the auditory brainstem (Levitt and Moore 1979) and that the neural activity of the reticular formation therefore also influences the processing of (new) incoming acoustic information.

Music Perception and Memory

The modules presented in Fig. 1 are associated with a variety of memory functions (Jäncke 2008). For example, the auditory sensory memory (along with Gestalt formation) is connected with both working memory (Berti and Schröger 2003) and long-term memory (Näätänen et al. 2001). Structure building requires working memory as well as a long-term store for syntactic regularities, and processing of meaning information is presumably tied to a mental “lexicon” (containing conceptual–semantic knowledge), as well as to a musical “lexicon” containing knowledge about timbres, melodic contours, phrases, and musical pieces (Peretz and Coltheart 2003). However, the

details about interconnections between the different modules and different memory functions remain to be specified.

Neuroimaging studies suggest that the phonological loop of verbal working memory (WM) and the “tonal loop” of working memory for pitch strongly overlap in nonmusicians (Hickok et al. 2003; Koelsch et al. 2009; Schulze et al. 2011a), involving the ventral premotor cortex (encroaching Broca’s area), dorsal premotor cortex, planum temporale, inferior parietal lobe, anterior insula, subcortical structures (basal ganglia and thalamus), as well as cerebellum. A study by Schulze et al. (2011b) showed that, in contrast to nonmusicians, musicians use specific neural sub-components of WM only during verbal (right insular cortex) or only during tonal WM (right globus pallidus, right caudate nucleus, and left cerebellum). These results revealed the existence of two WM systems in musicians: a phonological loop supporting rehearsal of phonological information and a tonal loop supporting rehearsal of tonal information. Note that differences between nonmusicians and musicians for tonal WM (and between verbal and tonal WM within musicians) were mainly related to structures involved in controlling, programming, and planning of actions, thus presumably reflecting differences in action-related sensorimotor coding of verbal and tonal information. That is, verbal and tonal WM rely strongly on action-related coding (Schulze et al. 2011a).

The knowledge about musical long-term memory is still rather limited. Functional neuroimaging data suggest that access to musical semantic memory involves the (left) middle temporal gyrus and that musical semantic representations (i.e., parts of a musical lexicon) are stored in (left) anterior temporal areas (Groussard et al. 2009, 2010). In addition, Watanabe et al. (2008) reported that retrieval of musical information involves the hippocampal formation and the inferior frontal gyrus. Further systematic research in these areas is needed to differentiate memory operations from operations of the modules described in Fig. 1; it is important to bear in mind that, especially in functional imaging experiments, both types of operations usually co-occur.

Music and Language

The previous sections provided a number of examples for cognitive processes (and their neural correlates) underlying the processing of music as well as of (spoken) language. Decoding of both music and speech information requires a fine-grained analysis of the spectral and temporal features of acoustic information (boxes “Feature Extraction I and II” in Fig. 1). The section on auditory feature extraction mentioned the acoustic equivalence of timbre and phoneme, and the *identification* of “phonemes” in language is thus presumably paralleled by the identification of “timbres” in music. However, the segmentation of phonemic information during language perception usually requires a higher temporal resolution compared to the music (because timbral information in music usually does not change as rapidly as phonemic information in language). This probably leads to the left-hemispheric weighting for the segmentation of phonemes during language perception, whereas segmentation of spectral information such as melodic information of speech prosody or musical melodies engages the right auditory cortex more strongly than the left auditory cortex.

Adequate processing of both music and speech also requires auditory sensory memory and auditory scene analysis/auditory stream segregation (see boxes “Auditory sensory memory” and “Gestalt formation” in Fig. 1), particularly in noisy environments (which are more common than the quiet auditory environments typical for experiments on language or music perception). The processes mediating the identification of chords (e.g., whether a chord is a major or a minor chord, whether a chord is presented in root position or in inversion, etc.; see box “Analysis of intervals” in Fig. 1) perhaps parallel those underlying the identification of word form (due to both words and chords having a stem or “root” from which different versions emerge); however, this remains to be specified.

The section on music-syntactic processing (see also box “Syntactic structure building” in Fig. 1) presented evidence for interactions between the processing of music- and language-syntactic

information at levels of morpho-syntactic processing, phrase-structure processing, and possibly word-category information (see the evidence for the interaction between the ERAN and LAN and the provisional evidence for an interaction between ERAN and ELAN). Beyond these early interactions between music- and language-syntactic processes, it appears that cognitive and neural resources are also shared during later stages of syntactic integration (see box “Structural reanalysis and repair” in Fig. 1; see also the *Shared Syntactic Integration Resource Hypothesis* and the *Syntactic Equivalence Hypothesis* described above).

Both speech and music perception involve premotor coding (Liberman and Mattingly 1985; Koelsch 2009b), and both music and language give rise to affective processes: With regard to language, the perception of affective prosody (Ethofer et al. 2009; Wittfoth et al. 2010) as well as the affective contents of words (Vö et al. 2009; Herbert et al. 2009) can elicit emotional responses; for a review of the neural correlates of music-evoked emotions, see Koelsch 2014.

Finally, the section on musical meaning illustrated that communication of meaning is not exclusively a linguistic domain, but that music can also convey meaningful information: The interpretation of extramusical sign qualities of musical information can prime representations of meaningful concepts, and such priming can emerge from different cognitive levels (e.g., from auditory feature extraction or from a more fine-grained analysis of intervals, see also Fig. 1). Moreover, structural relations give rise to intramusical meaning (suggested to be reflected in the N500).

Corresponding to these shared processes, there is considerable resemblance, overlap, and interaction between ERP components (and their neural generators) elicited during the perception of music or language: Processing of musical as well as of speech information evokes (a) FFRs originating from the auditory brainstem; (b) P1, N1, and P2 potentials originating from the auditory cortex; (c) MMN potentials originating from temporal and frontal cortical areas; (d) potentials of early

syntactic processing that interact with each other (ERAN/LAN) and receive main contributions from the (inferior) pars opercularis (BA 44i); (e) potentials of syntactic (re)integration/reanalysis and repair (P600); and (f) N400 effects reflecting semantic processing (probably originating from posterior temporal and inferior frontal cortex).

The illustrated overlaps between music and language show that “language” and “music” are different aspects of the same domain, or two poles of a rather continuous dimension, rather than being two strictly separate domains (the *music–language continuum*; Koelsch 2012). Spoken language has rhythm, melody, and timbre, and the illusory transformation from speech to song described by Diana Deutsch (Deutsch et al. 2011) shows that humans can perceive spoken language also as song (although individuals often do not realize this in everyday life). Once an individual puts emphasis in his/her utterances, the speech becomes more song-like, and many art forms, such as rap music or recitatives, are both song and speech. In addition, music is often structured according to a syntactic system, and during music listening, meaning emerges from the interpretation of musical information. Therefore, any clear-cut distinction between music and language (and thus also any pair of separate definitions for language and music) is likely to be inadequate or incomplete.

As mentioned already above, even individuals without formal musical training show sophisticated abilities with regard to the decoding of musical information, the acquisition of knowledge about musical syntax, the processing of musical information according to that knowledge, and the understanding of music. This finding supports the notion that musicality is a natural ability of the human brain. Such musical abilities are important for the acquisition and the processing of language: Infants acquire information about word and phrase boundaries (possibly even about word meaning) in part through different types of prosodic cues. Moreover, tonal languages rely on a meticulous decoding of pitch information, and both tonal and nontonal languages require an accurate analysis of speech prosody to

decode structure and meaning of speech. The assumption of an intimate connection between music and speech is corroborated by the reviewed findings of overlapping and shared neural resources for music and language processing in both adults and children. These findings suggest that the human brain, particularly at an early age, does not treat language and music as strictly separate domains, but rather treats language as “a special case of music” (Koelsch and Siebel 2005).

NDVis–Neuro

John Langton
VisiTrend, Boston, MA, USA

Definition

NDVis–neuro is a Java application that enables visualization and analysis of model neuron simulation databases. It is open source and available at <http://ndvis.sourceforge.net/>. The tool was originally created to visualize the database described in “Alternative to hand-tuning conductance-based models: construction and analysis of databases of model neurons” (Prinz et al. 2003). It has now been used with a number of different databases generated by simulating neuron models with various input parameters.

Detailed Description

The examples and visualizations shown here are based on the Prinz database referenced above. The neuron model used to create the database contained eight conductance parameters: Na, CaT, CaS, A, KCa, Kd, H, and leak. Each parameter had six possible starting values. A simulation was run for every possible combination of the eight parameter values, yielding 6^8 or 1,679,616 simulations. For each simulation, the conductance parameters served as inputs and represented the initial state of the neuron model. Each simulation ran until neuron activity reached a steady state, or some time threshold was reached. Various attributes of the simulation output were measured and recorded in a database. This process included classifying models based on activity patterns in the simulation output. Figure 1 shows examples of four activity patterns labeled as follows: (A) silent, (B) tonically active or “spiking,” (C) bursting, and (D) nonperiodic (meaning there is no clear repetition of specific behavior).

Figure 2 shows a screenshot of NDVis–neuro visualizing the Prinz database. The visualizations combine two techniques: pixelization and dimensional stacking. Pixelization maps each data point (or simulation) to a single pixel. Dimensional stacking projects multiple dimensions onto the axes of a two-dimensional display (as labeled in Fig. 4). The goal is not to detect detail in a single pixel but to discover patterns and relationships across the data. For instance, a visualization can

NDVis-Neuro, Fig. 1 Four types of neuron activity

NDVis-Neuro, Fig. 2 NDVis-neuro visualizing model neuron simulation output classified according to activity type as defined in Fig. 1. Each pixel corresponds to one simulation and is colored as follows: bursting models are

blue, silent models are green, and a range of tonically active models range from light yellow to dark red to show the range in spike frequency

reveal boundaries between neuron activity types and reveal the conductance parameter values that create them. The tool can connect to any Structured Query Language (SQL)-compatible

database with any number of tables. It expects each row to represent one simulation and requires columns for the input parameters. Additional columns may contain measurements taken on

simulation output such as the duration of bursts in bursting neurons as shown in Fig. 1.

In Fig. 2, every pixel corresponds to one neuron model simulation and the color is mapped to some measure on the simulation output (e.g., classification of the neuron activity pattern). The mapping from data to pixel color is controlled through NDVis’ ColorMapper tool, as shown in Fig. 3. The user can specify an SQL query of arbitrary complexity and map the results to a discrete color or a color gradient. In the first row of the table in Fig. 3, the user selects models with spiking output (i.e., output that is classified as “activity = 0”), but only if it has a period (“p”) or spike frequency within a certain range. The user has assigned the color pink which will be mapped to pixels that represent models returned by the query. The rest of the rows have almost the same query but select different values for the range of “p”. This query set essentially uses color to show changes in spike frequency based on parameter values. Only discrete colors are assigned in Fig. 3. However, scalar values can also be mapped into a color gradient by picking two colors in the second column. For instance, the user could have simply selected “p” in the query without specifying a range. They would then pick two colors in the second column which represent the beginning and ending hues of a color gradient. NDVis-neuro normalizes scalar values and maps them into a gradient between the two color selections.

User queries in the ColorMapper tool are not limited to selecting values from the database.

They can perform any SQL function on the data and map the return value into the visualization. For instance, a common use is to take the log of certain values so that they better fit within a color gradient representation.

NDVis maps multiple parameters to the axes of a two-dimensional visualization using a technique called dimensional stacking (LeBlanc et al. 1990). Figure 4 shows an example with clearly labeled axes. On the X-axis, the visualization is first segmented according to the six values CaS can take on. Each of those segments is then segmented according to the six values that A can take on. Each A segment is segmented for the six values that Na can take on, and each of those segments contains every value for H (at the pixel level). The same general structure is repeated for the Y-axis. There is no need for every parameter to have the same number of possible values (as is the case in this example). NDVis was engineered to support models with different numbers of parameters and possible values. Mixed radix computation is used to mathematically map from parameter values to pixel coordinates and vice versa. Each parameter is treated as one digit in the value for either the X or Y coordinate. In our example we have eight parameters that can each take on six possible values. To derive a value for the X coordinate, we can concatenate four parameters and treat them as a four-digit, base six number. We convert the base six number to base ten to get the coordinate value. The Y coordinate can be computed in the same way from the remaining

NDVis-Neuro, Fig. 3 ColorMapper used to define apping from data to visualization

four parameters. An example of this computation using the parameter order in Fig. 4 is as follows:

$$X = \text{CaS?}6^3 + \text{A?}6^2 + \text{Na?}6^1 + \text{H?}6^0$$

$$Y = \text{CaT?}6^3 + \text{leak?}6^2 + \text{Kd?}6^1 + \text{KCa?}6^0$$

Note that parameter order does matter and can dramatically change the visualization. Different orders can reveal different insights. There is no optimal parameter order; however, certain parameter orders can reveal more or less information than others. NDVis-neuro enables users to change

the parameter order and refresh the visualization. This is done using the one-row table at the top of Fig. 2. The first four columns of the table represent parameters that are mapped to the X-axis, while the last four columns represent parameters that are mapped to the Y-axis. The user can drag and drop the columns of the table to reorder dimensions then refresh the visualization. Some versions of the tool have machine learning algorithms for finding informative parameter orders. For instance, genetic algorithms can be used along with image analysis which computes entropy (i.e., information content) as a fitness function

NDVis-Neuro, Fig. 4 NDVis image projecting eight parameters into two dimensions

based on color variation across the visualization. The general idea is that an image that clusters similarly colored pixels will reveal information. However, within dimensional stacking, a cluster can also appear as repeating patterns rather than a solid block of color.

NDVis–neuron is no longer supported actively; however, it is open source and anyone may use or contribute its code.

[Equilibrium potential](#)

Definition

The Nernst equation describes how the equilibrium potential for an ion species (also known as its Nernst potential) is related to the concentrations of that ion species on either side of a membrane permeable to the ion.

Detailed Description

Physical Basis of the Equilibrium Potential

The membrane potential is the electric potential difference that exists across a membrane which is permeable to an ionic species and which separates solutions of the ionic species at differing concentrations. For example, cell membranes are often permeable to potassium, and the concentration of potassium inside the cell is greater than the concentration outside the cell. Negatively charged anions balance out the positive charge of potassium ions so that the charge inside and outside the cell is neutral, and the membrane is assumed to be impermeable to the anions (Fig. 1).

In this situation, potassium ions from the more concentrated solution inside the cell will tend to diffuse through the membrane to the lower-concentration solution outside. Because potassium ions are positively charged, this will cause a build-up of positive charge on the outside of the cell membrane and an equal and opposite build-up of negative charge on the inside. Thus, the electric potential outside the cell is greater than that inside, and the membrane potential, by convention defined as the potential inside minus the potential outside, will be negative. This potential difference corresponds to an electric field that exerts an inward force on the potassium ions, thus opposing their diffusion down the concentration gradient

Nernst Equation, Fig. 1 A cell containing high, balanced concentrations of potassium ions and anions inside and low, balanced concentrations of the same ions outside. The membrane is permeable to the potassium ions but not the anions. At equilibrium, the outside of the membrane is positively charged relative to the inside, which gives rise to the equilibrium membrane potential

from inside to outside. The potential difference at which the electric and diffusive influences on the ions balance out is known as the equilibrium potential or the Nernst potential. At this potential, there is no net flow of the ion species through the membrane.

The Nernst Equation

In a cell, the Nernst equation (Nernst 1888) relates the equilibrium potential E_X for an ion of type X with valency z_X to the concentrations $[X]_{\text{out}}$ and $[X]_{\text{in}}$ of the ion outside and inside the cell:

$$E_X = V_{\text{in}} - V_{\text{out}} = \frac{RT}{z_X F} \ln \frac{[X]_{\text{out}}}{[X]_{\text{in}}}$$

where F is Faraday's constant, R is the molar gas constant, and T is the temperature in kelvins.

Examples

1. The intracellular and extracellular concentrations of potassium ions in squid giant axon are $[K^+]_{\text{in}} = 400 \text{ mM}$ and $[K^+]_{\text{out}} = 20 \text{ mM}$, respectively. Since potassium ions carry a single positive charge, the valency $z_K = 1$, and using the values of $R = 8.314 \text{ J K}^{-1} \text{ mol}^{-1}$ and $F = 9.648 \times 10^4 \text{ C mol}^{-1}$, the equilibrium potential for potassium at 6.3°C (279.3 K) is obtained by substituting these values into the Nernst equation:

$$E_K = \frac{8.314 \times 279.3}{+1 \times 9.648 \times 10^4} \ln \frac{20}{400} = -72 \text{ mV}$$

2. The intracellular and extracellular concentrations of chloride ions in squid giant axon are $[Cl^-]_{\text{in}} = 40 \text{ mM}$ and $[Cl^-]_{\text{out}} = 560 \text{ mM}$, respectively. Since chloride ions carry a single negative charge, the valency $z_{Cl} = -1$, and the equilibrium potential for chloride at 6.3°C is

$$E_{Cl} = \frac{8.314 \times 279.3}{-1 \times 9.648 \times 10^4} \ln \frac{560}{40} = -64 \text{ mV}$$

Derivation

The Nernst equation can be derived from the Nernst-Planck equation of electrodiffusion (Johnston and Wu 1995; Hille 2001; Sterratt et al. 2011). Diffusion is assumed in one dimension (labeled x), through the membrane. At equilibrium, no current flows, so the flux in the Nernst-Planck equation is set to zero to give: $\frac{1}{[X]} \frac{d[X]}{dx} = -\frac{z_X F}{RT} \frac{dV}{dx}$. This equation can be rearranged and integrated: $\int_{V_{\text{in}}}^{V_{\text{out}}} -dV = \int_{[X]_{\text{in}}}^{[X]_{\text{out}}} \frac{RT}{z_X F [X]} d[X]$. The Nernst equation results from evaluating this integral.

Alternatively, the Nernst equation can be derived from thermodynamic principles (Hille 2001).

Definition

The Nernst-Planck equation is a physical reformulation of Fick's macroscale diffusion law, extended to the motion of charged particles. The equation was established and experimentally underpinned by Nernst, and theoretically elaborated by Planck, and acquired growing significance when it was recognized that essential processes of life, such as cellular excitation and mitochondrial energy metabolism, depend on electrodiffusion.

Detailed Description

Derivation of the Steady-State Nernst-Planck Equation

Nernst (1888) started from van't Hoff's (1887) insight that solute particles generate, in a solvent, an osmotic pressure that obeys the gas laws, and from the observation that they move, under the influence of a constant force, at constant mean velocity owing to the enormous friction forces generated by collisions with solvent molecules.

Let the mobility μ of a particle be the velocity v it acquires under the influence of a unit force F (Benedek and Villars 2000):

$$\mu = \frac{v}{F}$$

(in units of time/mass). Then the flow density or flux J (the number of particles passing through a surface perpendicular to the direction of particle motion, during a time interval dt , in units of moles $\text{m}^{-2} \text{s}^{-1}$) will be proportional to the speed v and concentration c :

$$J_k = v_k c_k$$

Clearly, on a slice of cylinder centered at x and of width dx and area A , the particles of species k generate a diffusion force dp_k , which is the difference in osmotic pressure p_k measured over the distance dx (Fig. 1). Given that the number of particles of species k in the slice equals $c_k N dx$, where N is Avogadro's number and c_k the particle concentration, the force per particle is

Nernst-Planck Equation, Fig. 1 Diffusion cylinder of cross-sectional area A , indicating the osmotic pressure gradient for ion species k at position x

$$-\frac{A dp_k}{A c_k N dx},$$

and the velocity

$$v_k = -\mu_k \frac{1}{N c_k} \frac{dp_k}{dx}$$

Hence, the flux

$$J_k = -\mu_k \frac{1}{N} \frac{dp_k}{dx},$$

or, using the ideal gas law,

$$J_k = -\mu_k \frac{RT}{N} \frac{dc_k}{dx}$$

(R being the gas constant and T the absolute temperature in kelvins).

From Fick's law, one also concludes that the diffusion coefficient D_k relates to μ_k as $D_k = \mu_k \frac{KT}{N} = \mu_k k_B T$, k_B being Boltzmann's constant.

Nernst then postulated that when a compound dissolves and dissociates into ions, the difference in diffusion coefficient between the ions must induce an electric field $E(x)$ that enhances the speed of the slower ion and slows down the faster, so as to make both ions diffuse at the same speed. More particularly, in an electric field $E = -\frac{d\phi}{dx}$, a positively charged particle of valency z_k is acted on by a force $z_k e E$, where e represents the unit charge. Hence, the particle's velocity is $\mu_k z_k e E$, and its flux $\mu_k z_k e E c_k$.

Taken together, the flow densities or fluxes J_i^+ and J_j^- for each positively charged ion i and each negatively charged ion j are

$$J_i^+(x) = -\mu_i^+ \left(k_B T \frac{dc_i^+}{dx} + z_i^+ e c_i^+ \frac{d\phi}{dx} \right)$$

$$\frac{\partial c_i^+}{\partial t} = \mu_i^+ \left(k_B T \frac{\partial^2 c_i^+}{\partial x^2} + z_i^+ e \frac{\partial}{\partial x} \left(c_i^+ \frac{\partial \phi}{\partial x} \right) \right)$$

$$J_j^-(x) = -\mu_j^- \left(k_B T \frac{dc_j^-}{dx} - z_j^- e c_j^- \frac{d\phi}{dx} \right)$$

$$\frac{\partial c_j^-}{\partial t} = \mu_j^- \left(k_B T \frac{\partial^2 c_j^-}{\partial x^2} + z_j^- e \frac{\partial}{\partial x} \left(c_j^- \frac{\partial \phi}{\partial x} \right) \right)$$

An equivalent formulation, using the above relationship between D_k and μ_k , and the identity $\frac{RT}{F} = \frac{k_B T}{e}$, reads

$$J_k(x) = -D_k \left(\frac{dq}{dx} + \frac{F z_k}{RT} c_k \frac{d\phi}{dx} \right),$$

where the valency z_k now takes negative integer values for anions and positive values for cations.

To obtain the steady-state ion current density I_k , the flux J_k must be multiplied by $z_k F$.

As noted by Nernst (1888), other flux terms can be added, representing gravitational, centrifugal, or magnetic forces. Planck (1890a) extended Nernst's equation to three spatial dimensions (Modeling Ion Concentrations). He also added Poisson's equation, which is a reformulation of Coulomb's law, to quantify the charge involved in generating the electrostatic field E :

$$\begin{aligned} \nabla^2 \phi(x) &= \nabla \cdot \text{grad}(\phi(x)) = \nabla \cdot E(x) = -\frac{\rho(x)}{k\epsilon_0} \\ &= -\frac{F}{k\epsilon_0} \sum_k z_k c_k(x) \end{aligned}$$

where ϵ_0 is the permittivity of free space and κ the dielectric constant of the solvent (assuming a homogeneous medium).

The Time-Dependent Nernst-Planck Equations

Planck (1890a) formulated the time-dependent equation (equivalent to Fick's second law). From the continuity constraint

$$\frac{\partial c_k}{\partial t} = -\frac{\partial J_k}{\partial x}$$

one derives

The electric current $I(x,t)$ must now be supplemented with the displacement current (Cohen and Cooley 1965):

$$I_D = \kappa \epsilon_0 \frac{\partial E}{\partial x}$$

Solutions of the Nernst-Planck Equations

Solving the full Nernst-Planck equations requires solving for each ion species separately, along with Poisson's equation. Note that the coupled set of equations is very nonlinear, due to the product of the ionic concentration with the strength of the electric field, which itself is determined by the distribution of charges. The system can be solved numerically after expressing the equations in integral form (Cohen and Cooley 1965; Arndt and Roper 1972). For many applications, however, reasonable assumptions can be made, such as zero or steady-state current, the presence of only monovalent ions, symmetries in the ionic compositions of the separated solutions, electro-neutrality, linear concentration gradients, constant electric field, etc. These assumptions enable analytic solutions to be obtained that have proven to be in close agreement with both experimental observations and numerical simulations.

For instance, Planck (and Nernst), instead of solving Poisson's equation, assumed electro-neutrality everywhere:

$$c_1^+ + c_2^+ + \dots = c_1 + c_2 + \dots$$

Note that this approximation still allows finite potentials to be obtained, provided the permittivity in the right-hand side of Poisson's equation vanishes as well (which is equivalent to assuming an infinite speed of light). Planck (1935) argued that the electrostatic field establishes so fast, and

involves the separation of so little charge over so little distance, that the resulting effects on concentration, and hence on the calculation of the field, are negligible. In contrast to this, on a macroscale, diffusion is a very slow process (on a microscale it can be extremely fast!) – Nernst used units of days and centimeters.

Nernst's Diffusion Potential

Nernst (1888, 1889) calculated the field E that establishes in a solvent across the concentration gradient $c(x)$ of a compound dissociating into ions having different diffusion coefficients (a generalization of Fick's first law to charged particles). For the dissociation into a univalent anion and cation, zero electric current ($J^+ = J^-$) requires

$$k_B T (\mu^+ - \mu^-) \frac{dc}{dx} = -e(\mu^+ + \mu^-) c(x) \frac{d\phi}{dx}$$

and hence,

$$\frac{d\phi}{dx} = -\frac{k_B T}{e} \left(\frac{\mu^+ - \mu^-}{\mu^+ + \mu^-} \right) \frac{1}{c} \frac{dc}{dx}$$

Nernst's diffusion potential generalizes, for arbitrary distributions of monovalent ions, to

$$\frac{\partial \phi}{\partial x} = -\frac{k_B T}{e} \frac{\frac{\partial(U-V)}{\partial x}}{U+V}$$

where

$$U = \mu_1^+ c_1^+ + \mu_2^+ c_2^+ + \dots$$

$$V = \mu_1^- c_1^- + \mu_2^- c_2^- + \dots$$

The Nernst Potential

The electric potential needed to cancel for a particular ion species k the flux generated by its concentration gradient is called the Nernst potential E_k and can be derived by solving for $J_k = 0$. The equation for the Nernst potential is just a restatement of the Maxwell-Boltzmann equation:

$$c_k(x) \propto e^{-\frac{z_k e \phi(x)}{k_B T}}$$

confirming that at equilibrium, the distribution of particles satisfies the distribution of energies due to thermal agitation.

Planck's Solution for the Diffusion Potential

In order to obtain the potential difference $\Delta\phi$ between two locations, the electric field E between them must be integrated, which generates a problem when two different ionic solutions have a planar interface where the derivative of concentration with respect to space becomes infinite. This discontinuity can be removed by assuming the presence of a transition zone, but Planck (1890b) recognized that $\Delta\phi$ now depends on the exact shape of the concentration gradient $\varphi(x)$, and hence the field $E(x)$, within the transition zone.

Planck obtained the exact solution for solutions of monovalent ions at thermodynamic equilibrium $\frac{\partial c_k}{\partial t} = 0$, for each ion species k . However, Planck's solution may require solving a transcendental equation.

Henderson's Solution for the Diffusion Potential

Henderson obtained a simpler solution, for the constraint that at each given position of the junctional zone, all ions form identical mixtures of their concentrations across the boundary (the simplest case being each species varying linearly, but the solution is not limited to this). Henderson's formula reads for the interface between a c_1 molar NaCl solution and a c_2 molar KCl solution as (Benedek and Villars 2000)

$$\Delta\phi = -\frac{k_B T}{e} \frac{(\mu_{K^+} - \mu_{Cl^-})c_2 - (\mu_{Na^+} - \mu_{Cl^-})c_1}{(\mu_{K^+} + \mu_{Cl^-})c_2 - (\mu_{Na^+} + \mu_{Cl^-})c_1}$$

$$\ln \frac{(\mu_{K^+} + \mu_{Cl^-})c_2}{(\mu_{Na^+} + \mu_{Cl^-})c_1}$$

For the general case of solutions of monovalent ions, Henderson's formula is

$$\Delta\phi = -\frac{k_B T}{e} \frac{(U_1 - U_2) - (V_1 - V_2)}{(U_1 - U_2) + (V_1 - V_2)} \ln \frac{U_2 + V_2}{U_1 + V_1}$$

Although Henderson's solution is different from Planck's equilibrium solution, it is often closer to experiment, because convection currents (not taken

into account in the Nernst-Planck equation) affect the ionic composition of the transition zone.

Goldman's Constant-Field Equation

Goldman (1943) applied in his study of rectifying membranes techniques used by Mott (1939) for semiconductors. Herein the stronger constraint is adopted that the electric potential $\varphi(x)$ within the transition zone varies linearly with position x . Although Planck's general solution generates a constant field E only under limited conditions, involving symmetries in the ionic compositions across the membrane ($[K^+]_{\text{inside}} = [Na^+]_{\text{outside}}$), Goldman's approximate solution offers the benefits of easier integration, as each Nernst-Planck equation now becomes linear and uncoupled.

A Note on the Hodgkin-Huxley Model

In the Hodgkin-Huxley model, the Nernst-Planck steady-state current for each ion species, say K^+ ,

$$I_{K^+} = -\mu_{K^+} F \left(k_B T \frac{dc_{K^+}}{dx} + ec_{K^+} + \frac{d\phi}{dx} \right)$$

is rewritten as

$$V = -\int_0^d \phi dx = \frac{k_B T}{e} \int_0^d \frac{d(\ln c_{K^+})}{dx} dx \\ + I_{K^+} \int_0^d \frac{dx}{\mu_{K^+} e F c_{K^+}}$$

The first term is the Nernst potential, and the current I_{K^+} could be taken out of the second integral because at steady state all current is position independent; hence, formally, this reduces to

$$I_{K^+} = g_{K^+} (V - E_{K^+})$$

with

$$(g_{K^+})^{-1} = \int_0^d \frac{dx}{\mu_{K^+} e F c_{K^+}}$$

To conclude, the Hodgkin-Huxley formalism replaces the diffusion term by its electric equivalent but loses the concentration dependency of the drift term. Some will therefore argue that its use

has become obsolete and that Goldman's equation is a better substitute.

Electrodiffusion Through Ion Channels

How well the Nernst-Planck equations can predict, at the microscale, electrodiffusion through ionic channels, is still being investigated. Even though it has been argued that at all biologically relevant time scales steady state can be assumed (Cole 1968), the size of the current will depend, as stated above, on the exact shape of the electric field and hence on the spatial distribution of charges within the channel. Fixed charges on channel proteins and on the membrane surface may impose boundary conditions, and as the thermal agitation of mobile charges will prevent their being completely shielded, the Poisson-Boltzmann equations may need to be simultaneously solved (Benedek and Villars 2000). The field within the channel will also depend on the concentration of the permeating ions within the pore and on the polarization charges they induce in the channel's wall (Eisenberg 1996). One recent technique is first to explore these parameters with Brownian motion simulations, before importing them into the Nernst-Planck equations (Song and Corry 2011).

Physical Constants

R , gas constant (pressure of N particles in 1 m^3 volume at 1 K): $8.3145 \text{ J mol}^{-1} \text{ K}^{-1}$.

F , Faraday's constant (the charge of N particles of unit charge): 96485 C mol^{-1} .

k_B , Boltzmann's constant: $1.3807 \cdot 10^{-23} \text{ J K}^{-1}$,

e , unit charge: $1.6022 \cdot 10^{-19} \text{ }^\circ\text{C}$,

N , Avogadro's number (number of particle in 1 g mole): $6.0221 \cdot 10^{23}$.

ϵ_0 , permittivity of vacuum: $8.85 \cdot 10^{-12} \text{ }^\circ\text{C V}^{-1} \text{ m}^{-1}$.

Definition

NEST, the *Neural Simulation Tool*, is optimized for large networks of spiking model neurons. NEST

includes a wide range of neuron and synapse models and provides high-level commands to create spatially structured networks. NEST is controlled through a Python-based interface and supports parallel simulation. NEST is available from www.nest-simulator.org under a GNU Public License.

Detailed Description

NEST is optimized for networks of neurons whose subthreshold dynamics can be described by a small number of differential equations. By default, NEST simulations operate on a fixed time grid. However, NEST also supports precisely timed spikes (Morrison et al. 2007b; Krishnan et al. 2018), combining the precision of event-driven simulators (Henker et al. 2012) with the efficiency of grid-based simulation. Furthermore, NEST allows the simulation of neurons coupled by gap junctions (Hahne et al. 2015) and of networks of rate-based neurons (Hahne et al. 2017).

NEST supports hybrid parallelization combining MPI processes with OpenMP threads, permitting lightweight thread-only parallelization for small simulations on laptops as well as brain-scale simulations with nearly two billion neurons and eleven trillion synapses on supercomputers (Kunkel et al. 2014) and is ready for exascale supercomputers (Jordan et al. 2018).

PyNEST is the most widely used user interface for NEST (Eppler et al. 2008; Zaytsev and Morrison 2014), integrating NEST simulations with scripting and data analysis in Python. NEST can be controlled through PyNN (Davison et al. 2008) and can interact at run-time with other simulators through MUSIC (Djurfeldt et al. 2010).

New models can be added to NEST by writing an extension module in C++ which are dynamically loaded into a running NEST instance.

For an introduction to NEST usage, see Gewaltig et al. (2012).

Implementation

The core of NEST is a C++-application managing neurons, connections, and spike exchange. Each neuron model specifies an appropriate solver for its dynamics: linear models are solved using exact

integration (Rotter and Diesmann 1999), whereas the integration of nonlinear models is usually delegated to external solvers.

Parallel simulation of large networks is based on the concept of *virtual processes* (VP). VPs can be divided between MPI-processes and threads to optimally exploit the capabilities of the underlying hardware; NEST ensures identical results if the number of VPs is fixed (Plesser et al. 2007).

History, Development, and Applications

NEST started out as a student project by Markus Diesmann and Marc-Oliver Gewaltig called SYNOD (Diesmann et al. 1995). The simulator was renamed NEST in 2001 and was first released to the public in 2004. As of October 2012, NEST is available under a GNU Public License from www.nest-simulator.org, and since 2015 code development is hosted on Github (<https://github.com/nest/nestsimulator>). NEST development is driven by specific research needs (Kunkel et al. 2010), generating a steady evolution of simulator capabilities, including parallelization (Morrison et al. 2005), precise spike timing (Morrison et al. 2007b; Krishnan et al. 2018), spiketime-dependent (Morrison et al. 2007a) and neuro-modulated plasticity (Potjans et al. 2010), and spatially structured networks (Plesser and Enger 2013).

To ensure software quality, NEST source code has been version-controlled since 1996, checked against an automated testsuite since 2008 (Eppler et al. 2009), and subject to continuous integration testing since 2012 (Zaytsev and Morrison 2013), and mandatory code review since 2015.

NEST has been taught at numerous summer schools around the world and is a key simulation tool in the European Human Brain Project. Since 2015, the NEST community meets annually at the NEST Conference. NEST is used today for a wide range of applications in computational and theoretical neuroscience, brain modeling, and neurorobotics.

Complex network theory in neuroscience; Graph theory in neuroscience

Definition

Network theory is a branch of mathematics concerned with the analysis of the structure of graphs, the mathematical abstraction of networks. Since the beginning of the twenty-first century, it has become an applied discipline due to the availability of large datasets for social,

technological, and biological systems. Although network theory was initially restricted to topological analysis, it has soon become a tool for understanding the emergence, functioning, and evolution of networks and the dynamical processes occurring on them. The application of network theory to neuroscience and, more specifically, to the analysis of brain structure and function represents a qualitatively different view of brain activity and brain-behavior mapping, shifting from a computerlike to a complex system vision of the brain, where networks are endowed with properties which stem in a non-trivial way from those of their constituent nodes. The network approach allows addressing an entirely new set of issues, such as detection and description of modularity and hierarchical structure, evaluation of efficiency and vulnerability, and structure-function relationships in healthy brains and disease.

Detailed Description

Background

The brain can be understood as a network of cells forming a massively parallel system, organized to carry out three major functions: computation, information transport, and communication among computational structures.

Brain tissue can be separated into gray matter (neurons) and white matter fibers connecting neurons (axons and dendrites). The human brain consists of roughly 10^{10} – 10^{11} neurons. Each neuron has approximately 10^4 synapses, which directly connect it to other neurons. The total wiring in the human cortical gray matter is of the order of 10^5 – 10^6 km, resulting in an overall neuronal potential bandwidth of the order of the terabit/second. Furthermore, the brain performs an estimated 10^{15} synaptic operations per second, but only consumes around 12 W, thus achieving an operation/joule ratio several orders of magnitude higher than the fastest available microprocessors (Sarpeshkar 1997).

On the other hand, powering the human adult brain accounts for ~20% of resting energy consumption (~60% in infants). Neuronal signal

transmission through axons and synapses accounts for about 50% of the brain's overall consumption (Laughlin and Sejnowski 2003), and due to the dense interconnected structure of its axons and synapses, the cortical gray matter uses more than 75% of total energy consumption for signaling. The energy supply limits both the total size and the amount of information that can be transmitted within the brain at a time.

The brain achieves these impressively high levels of computational efficiency by adopting energy-efficient architectures, involving trimming of superfluous signals and the representation of information with energy-efficient codes, resulting in appropriate distribution of the signal in space and time (Laughlin and Sejnowski 2003).

Brain Anatomy and Functional Activity

Human brain anatomy is characterized by networks of coupled neural systems across many spatial scales. Vertical structures divide the cortex into six main layers, within which basic computational units can somehow heuristically be defined as *minicolumns*, consisting of dense local interconnections between excitatory cells and inhibitory interneurons. Couplings between these local regions arise through sparse long-range excitatory projections, such as cortico-cortical fibers. These couplings facilitate large-scale integrative processes involving coordination between specialized networks.

Functional brain activity consists of transient episodes of synchronized/desynchronized activity between different parts of the brain (Breakspear 2002). Synchronization may facilitate integrative functions, by transiently binding together spatially distributed neural populations in parallel networks during sensory perception and information processing (Singer 1995; Miltner et al. 1999). Desynchronization may allow the brain to flexibly switch from one coherent state to another (Rodriguez et al. 1999). Asynchronous (nonlinear) couplings may also play an important role in functional integration, facilitating the creation of transient context-sensitive coherent neural assemblies between distant brain regions (Friston 2000).

Brain Connectivity

A network representation arises naturally both for the brain's anatomy and its functional activity. Brain networks can be defined at different scales, from the micrometer scale to the millimeter or centimeter scale of system-level neural assemblies, corresponding to the spatial resolution of the brain imaging technique used to define them.

For anatomical brain networks, it is straightforward to identify nodes as neurons or cortical areas and edges with axons or fiber tracts. On the other hand, when considering *functional connectivity*, networks are defined where edges correspond to correlated activity at different brain regions. Finally, *effective connectivity* can be associated to networks with directed edges whenever activity at one node modulates activity at another node (Sporns et al. 2004).

The classical approach to brain connectivity reflects the two basic ingredients of early neuropsychology: localization of cognitive function into specialized brain modules and the role of connection fibers in the integration of various modules. Thus, the emphasis is on the *identity* of the particular nodes and links forming the networks, under the covert hypothesis that each node and each link provide a unique contribution to the structure and function of the brain. The general model is that of a computerlike box-and-arrow one: by and large, computations are carried out within nodes, with links essentially working as pipes in a hydraulic system. Connectivity analysis is typically used to validate simple models of a given aspect of brain activity, and networks with only a few nodes and links are considered. The overall meaning of a given network can be traced back to the sum of its parts: an interpretation of a given connectivity pattern is in general proposed based upon the precise identity of its constituents' properties and on their known properties.

The Complex Network Approach

Over the last decade, brain structure and function have started been investigated using *complex network theory* (Boccaletti et al. 2006; Newman 2010), a statistical physics approach to an old branch of pure mathematics: graph theory.

Graph theory studies the properties of the formal mathematical structures called graphs, which are representations of a set of objects where some pairs of objects are connected by links. Complex network theory focuses on how *real* networks are organized and aims at identifying the guiding rules behind observed structures and dynamics of observed networks. For instance, nodes and links can both be endowed with dynamical properties and resulting collective behaviors such as synchronization can be investigated. It is also possible to study processes using the network as their support.

The way nodes and links are connected is associated with a great number of topological and dynamical properties at all scales, from that of the node to that of the whole network, which eventually allow neuroscientists to address many hitherto unaddressed issues.

Behavioral dynamics and its transitions are naturally described in terms of rewiring processes and the evolution of quantifiable network properties. Thus, network theory endows brain scientists with a potentially very high number of associated metrics of brain structure and activity, and brain *organization* receives a quantitative characterization. Moreover, it allows finding similarities and differences in the organization of neural networks, in spite of considerable variability in size and surface shape of individual brains.

The complex network approach represents a *qualitatively* different view of brain activity and brain-behavior mapping. The brain is understood as a complex system, where relationships between a *great number* of constituent parts give rise to collective behaviors. The spirit of the statistical physics approach hinges on an understanding of observed network properties as macroscopic phenomena resulting from microscopic interactions among a great number of individual components. Thus, in this approach, the identity of nodes and links is somehow lost. The network, rather than well-specified nodes or links, is endowed with specific properties. In general, these network properties are not easily traced to their single nodes and links; rather, they *emerge* from the *statistical properties* of their components.

With respect to prior connectivity methods, the complex network approach presents a range of distinctive *advantages*: first, it affords a *multi-scale* characterization of the brain's organization. Not only does network theory provide a description of network properties at microscopic, mesoscopic, and macroscopic scales, but it also naturally describes the *relationship across these scales*. Second, it allows handling complex relationships between brain structure, dynamics, and function. Third, it allows studying the brain as a biophysical machine and investigating a wide range of aspects of mechanistic brain functioning, including efficiency, resistance to failure, and synchronizability, which could not directly be addressed with connectivity techniques alone. Not only does network theory afford a quantitative description of directly observed states, but it also allows appraising the functional potential of healthy brains and the extent of the damage of those suffering from neurological or psychiatric pathologies.

Complex network theory therefore achieves three main *objectives*:

1. Singling out important anatomical and functional brain components
2. Characterizing general organizational principles of brain structure and function and as a consequence validating models of anatomical and functional brain organization, development, and pathology, as well as of cognitive function
3. Characterizing the brain, both anatomically and functionally, as a complex biophysical system whose constructive rules are subject to energetic constraints

Tools

What Is a Complex Network

A network consists of a group of N nodes (or vertices) connected through a set of L links (or edges). *Graph theory* focuses on the statistical properties of networks, mainly from a theoretical perspective. *Complex network theory* describes the analysis of real networks and the ways

topological structure determines the dynamical processes occurring in networks. Most real networks have an organization that is neither regular nor random. Complex network theory studies the laws that govern network topology and dynamics, the rules that lead to the formation of these non-random patterns, how topology influences the dynamics on top of the network, and the interplay between dynamics and the evolution of the network structure (Boccaletti et al. 2006; Newman 2010).

Building a Brain Network

The projection of experimental data onto a network is one of the most delicate steps in the application of network theory to the analysis of biological data. Both the nature (anatomical or functional) and the scale of observation constrain the way networks are reconstructed. The experimental technique used to record brain activity determines the size of the network and, ultimately, the information that can be extracted from it. Important methodological aspects of brain network reconstruction and possible pitfalls are still a subject of debate (Bialonski 2012; Zanin et al. 2012).

Brain networks can be classified into three main types: **anatomical, functional, and effective networks**.

Anatomical networks refer to the physical connections between neuronal elements, ranging from synapses between neurons to the grid of bundles between regions of interest (ROIs). We can define an anatomical network of connections at the scale we are interested in (or the scale given by experimental limitations): neurons, cortical columns, ROIs, or any parcellation of the brain with significant meaning. There exist different experimental techniques to trace the anatomical network of connections, which rely on both the scale and the organism being studied. For example, electron microscopy allowed extraction of the complete set of connections between neurons of the nematode *C. elegans* (White et al. 1986), the only living system whose nervous system has been fully mapped (Varshney et al. 2011). More recently, micro-optical sectioning tomography (MOST) has also revealed the connectivity of a mouse brain (Li et al. 2010). Both the anatomical

networks of the cat (Scannell et al. 1999) and the macaque (Felleman and van Essen 1991) cortex have been extensively studied thanks to the data obtained from different histological studies, leading to a complete cortico-cortical network of $N = 53$ cortical regions and $L = 650$ connections in the cat (Scannell et al. 1999) and the reconstruction of the macaque visual area ($N = 32$ and $L = 305$) (Felleman and van Essen 1991). Diffusion tensor imaging (DTI) (Iturria-Medina et al. 2007; Gong et al. 2009) allowed reconstruction of the human brain anatomical network, with the limitation of inferring the fiber bundle orientation. The use of diffusion spectrum imaging (DSI) has overcome this constraint (Hagmann et al. 2008) allowing an anatomical reconstruction of the human brain anatomical network formed by up to $N \sim 1,000$ nodes and $L \sim 100,000$ links (Hagmann et al. 2007).

Although the anatomical networks provide a substrate for the dynamical processes occurring on them, they are not necessarily linked to the functional activity occurring between different brain regions. Anatomical and functional networks may differ depending on the specific cognitive process that an individual is carrying out: while at short time scales the anatomical network is essentially static, the functional network associated with the execution of a cognitive task is inherently dynamical.

Functional networks account for the neurodynamical interactions between neural regions. Functional connectivity measures statistical interdependence between the dynamics of all pairs of the network nodes without taking into account causal effects. The more correlated the activity between two regions, the higher the weight of the functional connections between them. Note that despite the fact that functional connectivity requires the existence of an underlying anatomical connection, both functional and anatomical networks do not necessarily need to resemble each other (as the map of road connections does not necessarily reveal the traffic moving through them). As we will see, functional networks share common features between them, despite the fact that each network is task dependent.

There are different ways of measuring brain dynamics in order to later extract a functional

network. Electroencephalography (EEG) and magnetoencephalography (MEG) measure, respectively, the electric and magnetic fields created by the neuronal activity. Despite high temporal resolution (in the order of milliseconds) in both techniques, the spatial resolution is low (several centimeters) which leads to a poor reconstruction of the real dynamics of the brain. In addition, recordings are extracranial in both methodologies, which leads to problems of volume conduction in the case of EEG and common sources in MEG. Functional magnetic resonance imaging (fMRI) on the contrary, which monitors the brain activity by measuring the blood oxygenation, leads to a high spatial resolution ($\sim$ millimeters) paying the price of temporal resolution in the order of seconds.

Nevertheless, one of the main drawbacks of functional networks is the lack of directionality of their links. The fact that correlation does not imply causality leads to the necessity of defining an additional kind of brain networks. **Effective networks**, which are constructed from the analysis of the dynamical response of different brain sites, assign directionality to the links based on causality analysis (Büchel and Friston 2000). This kind of networks is the most mathematically demanding (Stephan and Friston 2007) but also the most accurate approximation to evaluate the real relations between brain sites.

Definitions and Notations

Tables 1 and 2 summarize the main node and network parameters, together with their mathematical definitions and the underlying concepts. Table 1 contains those parameters that concern to the node, although averaging over the whole network would lead to the extension of the parameter to the network level. Table 2 contains those parameters that only apply to network as a whole.

Important Parts of the Network

Degree and Strength Distributions

The degree k of a node simply accounts for the number of connections a node has. The degree distribution $p(k)$ of a network refers to the

probability of finding a node i with a certain number of connections k . When links are directed, the degree distribution is split into two: the in-degree (incoming links) and the out-degree (outgoing links) distributions. If links have a certain weight, then the degree distribution is transformed into the strength distribution $s(i)$, being the strength of a node, the sum of its links' weights. The degree distribution is a delta function in the case of regular networks and a Poissonian distribution when networks are completely random. Nevertheless, real networks show a diversity of degree distributions, with the majority of them being broad, with long tails. Additionally, in many cases, they can be described with a power-law decay ($p(k) \sim k^{-\gamma}$) (Newman 2003). In the case of the brain, different kinds of distribution have been reported depending on the spatial scale at which the system is analyzed, since the scale determines the number of nodes N and links L of the network which, in turn, constrains the width of the degree distribution. In cultured neural networks, the fact that neurons primarily connect through a random process leads to exponential distributions (Shefi et al. 2002). This kind of distribution is also reported in the in-degree and the out-degree of the anatomical connections of *C. elegans* nematode, the only living system with a whole reconstruction of its neural network (Amaral et al. 2000).

In human brain networks, the degree distribution strongly depends on the experimental technique used to acquire the data, the scale at which the system is observed, and the nature of the network that it is being analyzed (anatomical, functional, or effective). Hagmann et al. (2007) showed, by means of diffusion MRI, that a reconstruction of the anatomical brain network into 66 ROIs led to a degree distribution with an exponential decay. Later results (Hagmann et al. 2008) showed that though not having a power-law decay, a small group of hubs exists in both the degree and strength distributions. These functional hubs have high betweenness centrality and act as connectors between the main structural modules.

If we take a look at functional networks, the diversity of degree distributions increases.

Network Theory in Neuroscience, Table 1 Mathematical definition of the most significant node parameters

Node parameter	Mathematical definition	Underlying concept
Degree $k(i)$ and strength $s(i)$	$k(i) = \sum_{j \in N} a_{ij}$ $s(i) = \sum_{j \in N} w_{ij}$ where $a_{ij} = 1$ if nodes i and j are connected and $a_{ij} = 0$ otherwise. w_{ij} corresponds to the weights of the links in case they are considered	The degree accounts for number of links a node has. The strength is the sum of weights w_{ij} of the links arriving at a certain node (Amaral et al. 2000; Newman 2003)
Outreach $o(i)$	$o(i) = \sum_{j \in N} l_{ij} w_{ij}$ where l_{ij} is the length of the link between nodes i and j	Sum of the link's weight w_{ij} multiplied by the link's Euclidean length l_{ij} (Buldú et al. 2011)
Eigenvector centrality $e_c(i)$	$e_c(i) = \sum_{j \in V(i)} e_c(j)$ $V(i)$ being the set of neighbors of node i	A measure of node importance that takes into account the importance of the node's neighbor. It is equivalent to the eigenvector associated with the largest eigenvalue of the connectivity matrix (Newman 2010)
Shortest path d	Given two nodes i and j , the shortest path d_{ij} is the minimum number of nodes to be visited when going from i to j	Computes the minimum number of steps to go from one node to another (Newman 2010)
Clustering $C(i)$	$C(i) = \frac{2L_i}{k_i(k_i - 1)}$ where L_i is the number of links between neighbors of node i	It is related to the percentage of neighbors of a certain node that, in turn, are neighbors between them (Watts and Strogatz 1998). There exist other metrics that quantify the node clustering (Newman 2010)
Node betweenness $b(i)$	$b(i) = \sum_{j \neq k} \frac{n_{jk}(i)}{n_{jk}}$ where n_{jk} is the number of the shortest paths between nodes j and k and $n_{jk}(i)$ is the number of these paths that go through node i	Accounts for the number of the shortest paths between any node j and k of the network that cross node i (Newman 2010)
Within-module degree $z(i)$	$z(i) = \frac{k_i(m_i) - k(m_i)}{\sigma_{k(m_i)}}$ where $k_i(m_i)$ is the degree of node i inside its community and $k(m_i)$ and $\sigma_{k(m_i)}$ are, respectively, the average and the standard deviation of the degree inside the community	Measures the importance of a node inside its community (Guimerà and Amaral 2005)
Participation coefficient $p(i)$	$p(i) = 1 - \sum_m \left(\frac{k_i(m)}{k_i} \right)^2$ where $k_i(m)$ is the degree of node i inside community m	Evaluates the percentage of links that a node has to other communities (Guimerà and Amaral 2005)
Local efficiency $E_l(i)$	Computed as the global efficiency of the subnetwork $V(i)$ containing all neighbors of node i (see definition of Global Efficiency in Table 2)	Accounts for the inverse of the shortest path of the neighborhood of a node i when node i has been deleted. It is a measure of local resilience (Latora and Marchiori 2001)

It is possible to translate the majority of these metrics to the network level by simply averaging over the all nodes of the network. See (Rubinov and Sporns 2010) for the adaptation of these parameters to weighted networks

Eguíluz et al. showed that functional brain networks obtained from fMRI data show scale-free distributions for different tasks (Eguíluz et al. 2005) which could be related to their resistance to failure, facility of synchronization, and fast signal processing (Lago-Fernandez et al. 2000). Van den

Heuvel et al. (2008) also reported a scale-free distribution. Nevertheless, other results showed some discrepancies at the tail of the degree distribution, which was better fitted with an exponential decay leading to a power-law, exponentially truncated distribution (Achard et al. 2006a).

Network Theory in Neuroscience, Table 2 Mathematical definition of the most extended network parameters

Network parameter	Mathematical definition	Underlying concept
Assortativity r	$r = \frac{L^{-1} \sum_i j_i k_i - [L^{-1} \sum_i \frac{1}{2} (j_i + k_i)]^2}{L^{-1} \sum_i \frac{1}{2} (j_i^2 + k_i^2) - [L^{-1} \sum_i \frac{1}{2} (j_i + k_i)]^2}$ where $-1 \leq r \leq 1$ and j_i and k_i are the degrees of the nodes at the end of the i_{th} link, with $i = 1 \dots L$	Quantifies the degree correlation of the whole network. Assortative (disassortative) networks are those with positive (negative) degree correlations (Newman 2002)
Small-worldness S	$S = \frac{C/C_{ran}}{d/d_{ran}}$ being $C(d)$ and $C_{ran}(d_{ran})$, respectively, the clustering (shortest path) of the network and its randomized version	It evaluates the ratio between the normalized network clustering and the normalized shortest path. The highest the S , the more “small world” the network is (Humphries and Gurney 2008)
Synchronizability r and λ_2	$r = \frac{\lambda_N}{\lambda_2}$ (class III) λ_2 (class II) where λ_2 and λ_N are, respectively, the second smallest and the largest eigenvalues of the Laplacian matrix $L = K - A$, with K being a diagonal matrix containing the degree of the nodes and A the adjacency matrix	It is related to the stability of the synchronized state of the network. The dynamical system and the kind of coupling determine the class (I, II, or III), which is related to the ability of the system to synchronize (Boccaletti et al. 2006)
Global efficiency E_g	$E_g = \frac{1}{N(N-1)} \sum_{i \neq j} \frac{1}{d_{ij}}$ where d_{ij} is the shortest path between nodes i and j	Measures the harmonic mean of the inverse of the shortest paths between all nodes of the network (Latora and Marchiori 2001)
Modularity Q	$Q = \sum_{s=1}^{N_M} \left[\frac{l_s}{L} - \left(\frac{d_s}{2L} \right)^2 \right]$ where l_s and d_s are, respectively, the number of links inside community s and the average degree of the community. N_M is the total number of communities inside the network	Evaluates how good is a given partition of the network into communities by comparing the density of links inside each community with that obtained in an equivalent random network (Newman 2006)

These parameters only have a meaning when analyzing the network as a whole. There exists a translation of all of them to weighted networks (Rubinov and Sporns 2010)

Altogether, no unique function seems to describe the degree distribution of brain networks. The number of nodes and links of the network strongly constrains the width of the distribution, together with the experimental technique used to obtain the data and the task performed during the recordings.

Network Hubs and the Rich Club

Network hubs are those nodes with higher importance in the network structure. Different measures have been proposed to quantify the relevance of a node within a network. At a local scale, the node degree (or strength if the network is weighted) is a good approach for identifying hubs. If we take into account the global structure of the network, the *betweenness* and the *eigenvector centralities* are the most widely used indicators (Newman

2010). The former is related to the number of shortest paths that crosses a given node, while the second takes into account not only the number of connections but also the importance of the neighbors.

The existence of hubs in both anatomical and functional brain networks has been related to a reduction of the wiring cost of the network, since hubs behave as integrators and distributors of information through the network when combined with a few long-range connections to other brain modules. Several studies have focused on the identification of these hubs and their role inside their respective community (i.e., among the nodes tightly connected to them) and as connectors between different brain modules (Hagmann et al. 2008). The tracking of hub connectivity during aging has

shown an alteration of both its importance within its community and its participation in other network modules (Meunier et al. 2009b). Interestingly, hub failure, quantified in terms of loss of connectivity, has been associated with the emergence of different brain diseases (Bassett et al. 2008).

A number of recent studies investigated the interconnections *between brain hubs* as a potential substrate for central integrative processes. In both the human and the macaque cerebral cortices, a largely consistent set of brain regions termed the *rich club* turns out to be more densely interconnected than expected based on comparisons to degree-preserving null models, with a large number of short communication paths connecting two or more rich club regions to each other (Colizza et al. 2006; Harriger et al. 2012; Van den Heuvel et al. 2012). In the human brain, the rich club spans regions including the superior parietal cortex, the precuneus, both the posterior and anterior cingulate cortices, and the insula (Van den Heuvel et al. 2012). The brain's rich club appears as a "super hub" where information converges from and is broadcast back to segregated communities and networks, allowing for integrated processing, offering a potential network substrate for the "global neuronal workspace" proposed in recent influential theories of cognition (Shanahan 2012).

General Organizing Principles

Complex systems, of which the brain is an example *par excellence*, are typically characterized by structure at and within multiple scales and by a correspondence between topology and dynamical processes taking place on them. In the brain, it is clear that both topology and dynamics control function. In turn, function retroacts, possibly at much longer time scales, to optimize network topology and brain dynamics, producing topological communities corresponding to functional subdivisions in the brain. Complex network theory is ideally suited to extract the general rules governing these sophisticated spatiotemporal multiscale relationships.

Assortativity/Disassortativity

Assortativity is a measure of the degree-degree correlations within a complex network. First introduced by Newman in the context of complex networks (Newman 2002), the assortativity parameter r (see Table 2 for a mathematical definition) computes the Pearson correlation coefficient for the nodes of the same degree. In assortative (*disassortative*) networks, nodes of the same (different) degree are prone to be connected, often leading to the appearance of a *rich club* where nodes of higher degree have connections to each other. Hagmann et al. (2008) also reported assortative mixing in the anatomical network of the human brain, showing that hubs are prone to connect to each other. Functional brain networks obtained from fMRI recordings during music listening and finger tapping were shown to be assortative (Eguiluz et al. 2005). Interestingly, the majority of biological networks seem to be disassortative, with clusters organized around local hubs (Newman 2010).

Motifs

Motifs are structural organizations of small size (typically less than 10 nodes) that are overrepresented inside the topological structure of a complex network. Milo et al. (2002) showed that biological networks have certain building blocks, which they called motifs, which emerge as a consequence of an underlying function. The existence of motifs in brain networks reveals the existence of nonrandom rules for creating local connections, and the diversity of network motifs has been related to the enhancement of the processing capacities at the local level (Sporns and Kötter 2004; Sporns et al. 2007).

Modularity and Hierarchy

The modularity of a network accounts for the existence of densely connected groups of nodes that lead to the formation of network communities. The detection of network communities has several difficulties (e.g., the absence of a perfect network partition, the overlap between communities, the coexistence of modules of different size) and has been a field of intense research during the last years (Fortunato 2010). In addition, it is common to observe a hierarchy in the modular

organization which indicates that, at different scales, there exist different network partitions that, in turn, have hierarchical dependencies between them (Sales-Pardo et al. 2007; Meunier et al. 2010). Detecting and evaluating the modular structure of a brain network is a complex task, but it is mandatory since, first, it gives information about the well-known segregated activity of the brain and, second, part of the complexity of the dynamical processes occurring in the brain relies on the existence of network modules (Pan et al. 2010). Interestingly, anatomical networks exhibit a modular (Hilgetag et al. 2000) and hierarchical organization (Zamora-Lopez et al. 2010). Different community partition algorithms of anatomical networks have shown high correlations of the obtained communities with known functional localized areas in the human brain (Chen et al. 2008) and also allow identification of those regions that make the structural core of the network (Hagmann et al. 2008). But the wealth of this kind of analysis is increased when analyzing functional networks. A series of studies have tracked the modular structure of resting-state functional networks at different ages, showing an alteration of the connections between communities as a consequence of the aging process (Meunier et al. 2009b). A hierarchical organization of functional communities has also been reported in the human brain (Meunier et al. 2009a), and it seems to indicate that the hierarchically modular structures facilitate the embedding of complex topologies into low-dimensional physical space (Bassett et al. 2010).

Integration/Segregation

Consistent experimental and computational evidence shows that cognitive function requires an optimal balance between *global* integrative and *local* functionally specialized processes (Tononi et al. 1994, 1998; van Putten and Stam 2001). Cooperation between local and global processing was shown to be the basis of cooperative phenomena such as feature binding in gestalt-like perception, in which the emergence of a coherent percept from spatially distant stimuli is associated with synchronous responses of distant neuronal assemblies (Singer 1995).

An appropriate balance between these two tendencies has been shown to be necessary for efficient functioning, particularly in neural systems (Tononi et al. 1994); in fact, exceedingly segregated or integrated brains have been associated with various pathological conditions, e.g., autism (Just et al. 2004) or schizophrenia (Fletcher et al. 1999; Tononi et al. 1998).

It appears then that the functional organization of the human brain presents an essential trade-off: on the one hand, modules should be sufficiently independent to guarantee functional specialization and parallel computing. On the other hand, modules should be sufficiently connected to bind multiple sources of information to promote coordinated activity or coherent percepts.

Small Worlds and Fractal Networks

Small-World Property

Small-world structure, a particular topology combining high local clustering and short path length, has been suggested to represent a solution to the trade-off between module independence and specialization. The small-world property refers to a very small distance in a network's path length, as compared to the total number of network nodes. The idea of a small world appeared in 1929, in a short story by the Hungarian author Frigyes Karinthy called *Láncszemek* (*Chains*), and later made famous by Stanley Milgram's *six degrees of separation* experiment (Milgram 1967). Milgram's experiments showed that the average number of successive acquaintances (i.e., the distance) between any two individuals in a population of the order of billions is just six.

Small-world networks show a high local density of connections together with a short number of steps to go from one node to any other (Watts and Strogatz 1998). They are characterized by (i) a high clustering coefficient C , which measures the percentage of the first neighbors of one node that are, in turn, connected with each other, and (ii) by the existence of long-range connections that create shortcuts between distant regions of the network. On the other hand, scale-free networks are associated with a power-law degree distribution $P(k) \sim k^{-\gamma}$, where γ is the degree exponent; the

average distance $\bar{d}$ scales logarithmically with the network size as $\bar{d} \sim \ln N$. The scale-free nature of functional networks implies that there are always a small number of brain sites functionally connected to most other brain regions and that the number of these nodes is comparatively much larger in these networks than in randomly connected ones.

It has consistently been shown that brain anatomical networks have characteristically small-world properties of dense or clustered local connectivity with relatively few long-range connections mediating a short path length between any pair of neurons or regions in the network (Sporns et al. 2004; He et al. 2007; Hagmann et al. 2007). Similarly, human brain functional networks of coherent activity associated with the execution of cognitive tasks have also been associated with power-law or truncated power-law degree distributions (Eguíluz et al. 2005; Salvador et al. 2005; Achard et al. 2006b; Bassett et al. 2006; Achard and Bullmore 2007).

The small-world structure seems to be pervasive both across scales of brain activity and across species. Such a structure also characterizes functional cortical neuronal circuits in mammals (Song et al. 2005; Yu et al. 2008) and been identified in nervous systems as simple as that of the nematode *C. elegans* (Watts and Strogatz 1998).

The modifications of small-world structure in disease (Stam et al. 2007), in normal aging, and by pharmacological blockade of dopamine neurotransmission (Achard and Bullmore 2007) may be functionally interpreted in the light of theoretical studies showing that small-world architecture optimizes information processing (Strogatz 2001), facilitates synchronization (Bucolo et al. 2003) and rapid response and emergence of coherent oscillations (Lago-Fernandez et al. 2000), and confers resilience against pathological attack.

Fractal Networks

Because complex systems typically exhibit structure at many scales, it is extremely interesting to understand the behavior of a complex network under a scale transformation and see the degree of similarity across scales. Fractality in a complex network can be identified in a manner similar to

that of ordinary fractals, which are objects consisting of self-similar copies at all scales. In this process, the network is first covered with boxes. After optimally covering a network with boxes of a given diameter l_B , a renormalization transformation is applied where each box is replaced by a single node and the links of the original network are transferred to the renormalized one, so that original links between nodes belonging to different boxes constitute links between these boxes.

Under general conditions, the required number of boxes N_B scales with the box diameter l_B as $N_B \sim l_B^{-\gamma_B}$ and γ_B is the fractal dimension of the network. Thus, fractality indicates a power-law scaling of the distances with network size, which is very different from the logarithmic dependence of small-world structures.

The dependence of N_B on l_B highlights two main families of networks: fractal networks, displaying power-law scaling with a finite-valued exponent γ_B , and non-fractal networks with a sharp exponential decay of N_B with l_B and an infinite fractal dimension $\gamma_B \rightarrow \infty$. Several experimental studies have shown that brain networks show hierarchical, fractal structures (Meunier et al. 2010; Bassett et al. 2010).

In fractal networks hubs tend to connect to small degree nodes and not to each other. In other words, hubs tend to stay away from each other. As a result, centrality is weakly correlated with degree: due to the repulsion between hubs, small degree nodes appear at all parts of the fractal network. Thus, their centralities can have both small and large values, and their average centrality is significantly larger, resulting in transport properties that are different from those of networks with different topological organizations. Fractality is closely related with modularity: the isolation of hubs allows considering that each box is built around a local hub, so that boxes ultimately roughly correspond to a module. By comparison to scale-free networks, fractal networks should be more stable to hub damage. The isolation of hubs from each other may provide an explanation of why most biological networks evolved toward a fractal behavior.

Solving the Integration-Segregation Trade-Off: The Role of Weak Ties

Shortcuts generating small worlds and the persistence of modularity, a global property unrelated to local clustering, are intrinsically conflicting mechanisms. Clustering is a local quantity related to the immediate neighborhood of a node, while modularity is a global network property (Girvan and Newman 2002; Meunier et al. 2010; Fortunato 2010). Furthermore, the short distances of a small-world network are generally incompatible with strong modularity, which typically presents the properties of a “large world” (Song et al. 2005, 2006; Radicchi et al. 2008; Rozenfeld et al. 2010) characterized by long distances.

Gallos et al. (2012) presented a possible solution to the seeming trade-off between integration and segregation: while strong ties within the brain are hierarchically organized into modules with “large-world” self-similar properties, the addition of weak ties overcomes the repulsion between hubs, rendering the network non-fractal and small world (Watts and Strogatz 1998). Remarkably, weak ties are organized in a way that maximizes information transfer with minimal wiring cost, suggesting a natural solution to the paradox of efficient information flow in the highly modular structure of the brain (Gallos et al. 2012).

Topology and Dynamics

Topological aspects of brain anatomy and the dynamical processes taking place on them are mutually intertwined.

On the one hand, the topology of structural (anatomical) networks influences the dynamical processes (namely, synchronization) taking place within them (Boccaletti et al. 2006). The topology of brain connectivity was shown to be a control parameter guiding global brain dynamics through series of phase transitions corresponding to different observable patterns, so that a wide range of different behaviors can be accessed by varying coupling strengths (Jirsa and Kelso 2000). For instance, changes in the topology or synaptic strengths in the relevant networks can cause transitions between various regimes of activity

(i.e., from normal to seizing to bursting) in models of epilepsy (Netoff et al. 2004). This has important implications for neural networks, where synaptic coupling strengths can change at all temporal and spatial scales due to learning processes and plasticity.

On the other hand, the synchronization process unveils the emergence of hierarchical neural communities at different time scales (Arenas et al. 2006). Simulations showed that brain dynamics exhibits a modular hierarchical organization, where clusters coincide with the topological community structure of anatomical networks (Zhou et al. 2006). It was also shown that in the presence of (neurophysiologically plausible) weak synchronization between distant brain regions, dynamical clusters of brain activity closely reflect topological communities of brain anatomy, as areas that are important for long-range information integration; neuroanatomical connectivity patterns are univocally associated with given functional complexity levels; and networks capable of producing highly complex functional dynamics share common structural motifs (Sporns et al. 2000, 2002).

Synchronizability

Synchronization is one of the emerging dynamical processes, the understanding of which has benefited the most from network theory. The spectral analysis of the *adjacency* and *Laplacian* matrices of a network allows evaluation of the synchronization properties of the whole network and quantification of the stability of the synchronized state (Boccaletti et al. 2006; Arenas et al. 2008). The analysis of the eigenratio $r = \lambda_N/\lambda_2$ (see section “Tools”) of the *Laplacian matrix* showed that functional networks obtained for brain activity at rest and during the execution of a finger tapping task have a synchronizability parameter indicating that brain activity lies at a critical point separating the coherent/incoherent state of the whole network (Bassett et al. 2006). Interestingly, pathological dynamics, such as those reported during epileptic seizures, lead to an alteration of the network synchronizability, which recovers its adequate value just after the epileptic episode (Schindler et al. 2008).

Mechanical Principles of Brain Organization

When considered as a biophysical system, it is clear that the brain faces harsh energetic constraints limiting its computational capabilities (Laughlin and Sejnowski 2003), and that is influenced by its interactions with the environment and a range of potential sources of damage (as a result of trauma or degenerative damage). Correspondingly, it is interesting to understand how the brain faces its inherent trade-off between its information processing and transmission functions and the huge energetic costs that these suppose and how it prospers, withstands, or collapses in response to exogenous and endogenous events.

While understanding the general organizational principles of brain structure and function goes a long way into explaining the strategies that the brain uses to manage its economic dilemma in an optimal way (Bullmore and Sporns 2012), network theory provides valuable tools that allow for directly and quantitatively addressing this issue and through which insight as to how the brain would respond to various sources of attack can be gathered.

Efficiency

In the general context of complex networks, the concept of efficiency has been related to the ability of traveling through a network with the minimum number of steps. Latora and Marchiori introduced a parameter called *global efficiency* corresponding to the inverse of the shortest paths between any pair of nodes of the network (Latora and Marchiori 2001).

The concept of efficiency of a brain network relies both on the cost of creating and maintaining the network and the performance in executing a given task. It is important to see that such a metric is essentially tantamount to a topological distance, so that, when used in the context of brain networks, it would be wrong to interpret it as a quantifier of biological efficiency and of the ability of a given anatomical or functional network to perform a certain task.

Studies on the anatomical network of the *C. elegans* showed that the sparse structure of

connections between neurons (only 5% of the total number of possible links) leads to a reasonably high global efficiency, resulting in a high-performance background for information transfer (Latora and Marchiori 2001). Different studies have shown that, in brain anatomical networks, both the number of steps between any pair of nodes in the network (Kaiser and Hilgetag 2006) and the physical cost of their placement in a three-dimensional space (Bassett et al. 2010) are reasonably close to their optimal value.

Interestingly, the dynamical nature of functional networks allows them to adapt the trade-off between cost and efficiency during cognitive processes. Functional networks can enhance their efficiency during a demanding cognitive process, paying the price of an extra cost and recovering the initial (and more “economical”) state after finalizing the task (Kitzbichler et al. 2011).

Another fact that reinforces the hypothesis of the existence of a cost-efficiency balance in the brain is the analysis of impaired networks. The emergence of brain diseases appears to shift the whole network either to regimes with much higher costs, as is the case in schizophrenia (Lynall et al. 2010), or to organizations with low efficiency, for instance in Alzheimer’s disease (Stam et al. 2007).

Robustness

The robustness of a network is related to the impact of node/link deletion in the topological structure of the network (Cohen and Havlin 2010) and is classically quantified by measuring the deviations of the network parameters resulting from these deletions. The specific topology of a network determines its robustness. For example, scale-free networks maintain fairly well their structural properties when random failures are introduced in the network but turn out to be extremely fragile when hubs are the object of an attack (Albert et al. 2000). Anatomical networks of the cat and macaque showed a robustness similar to that of scale-free networks (Kaiser et al. 2007) due to the existence of hubs and the omnipresent modular structure of brain networks (Kaiser and Hilgetag 2004). Counterintuitively,

an increase in the network robustness is not necessarily associated with better performance of a brain network. For example, in the case of childhood-onset schizophrenia, the analysis of resting-state functional networks showed a decrease in the modular behavior of the network resulting in a more integrated structure and as a consequence an increased robustness to targeted attacks (Alexander-Bloch et al. 2010).

Modulating Network Properties

Temporal Evolution

The fact that brain networks are in continuous evolution demands that different analyses from those performed on static network properties be used. Specifically, what is needed is a perspective that would focus not only on the topology of the network but also on how it evolves in time. Interestingly, even in the absence of external stimulation, brain activity shows significant fluctuations in the network connectivity (Hutchison et al. 2012) with corresponding consequences in the topology of the functional network. At the fastest scales, functional networks emerge, evolve, and disappear according to the specific requirements of a given cognitive process. Several works have dealt with the evolution of functional brain networks (De Vico Fallani et al. 2008; Dimitriadis et al. 2010) showing that new information can be obtained when looking at the temporal evolution of functional networks. For example, Valencia and colleagues showed that during visual stimulation, the functional network maintains its small-world configuration, while, at the same time, functional connectivity is varying in time and frequency; network reconfiguration is also reported at larger time scales (Valencia et al. 2008). Bassett et al. followed the structure of functional networks during a learning process and demonstrated that the flexibility of the network topology is strongly correlated with the amount of learning in future sessions (Bassett et al. 2011). If we consider aging as the largest time scale that can be analyzed in the brain, again clear signs of reorganization are reported. While childhood is related to more disordered functional networks with progressive increase in

small-worldness (Boersma et al. 2011), a subsequent evolution toward a hierarchical modular structure has been reported, which seems to be optimized in maturity. Nevertheless, as aging advances the modular structure and its hierarchy are lost (Meunier et al. 2009b), showing the importance of this particular kind of configuration in the optimal functioning of brain networks.

Brain Diseases

Graph theoretical measures have proven to represent good indicators of the emergence and evolution of a series of brain diseases, an aspect that renders them of enormous practical application. The emergence of brain dysfunction can be quantified using network metrics, which are altered in a disease-specific way (Stam and van Straaten 2012). For example, during epileptic seizures, functional brain networks become more regular, modifying their degree distribution and losing part of their modular structure (Ponten et al. 2007; Kaiser and Hilgetag 2010). On the contrary, functional networks of schizophrenic patients become more random, with a consequent decrease of both the normalized clustering coefficient and shortest path (Micheliyannis et al. 2006). Mild cognitive impairment, a condition which sometimes evolves into Alzheimer's dementia, also shows increased functional network randomness, but in this case it is associated with increased network synchronization and a propensity to enhance long-range connections (Buldú et al. 2011). Network analysis of Alzheimer's disease indicates a disconnection syndrome leading to an increased shortest path and decreased network clustering, both leading to a severe impairment of the desirable properties afforded by small-world networks (Stam et al. 2009).

Future Lines of Investigation

Complex network theory has undoubtedly started opening new avenues on the understanding of brain networks. Still, some aspects of this methodology have yet more to offer as new lines of investigation open in the coming years. Four main lines seem to have a particularly promising future:

Quantitative Modeling of the Fundamental Principles of System-Level Brain Functioning

One of the merits of network theory is its ability to relate the topological structure of real networks to the processes occurring in them. It is possible to implement different network models which reproduce experimental observations or test new hypotheses with the aim of investigating the guiding rules behind the emergence, functioning, and evolution of anatomical and functional brain networks (Vértes et al. 2012). These models cannot be directly borrowed from other technological or biological fields and should contain the particular constraints of brain networks.

Predicting the Behavior and Evolution of Brain Networks

The fact that both anatomical and functional networks are in continuous evolution leads to the conclusion that we should pay attention not only to the observed network but also its future stages. Models that predict the evolution of a network would provide a fundamental contribution of complex network theory to the understanding of brain functioning.

Controlling and Targeting the State of the Network

Control and targeting of complex technological networks are two well-studied issues (Liu et al. 2011). Nevertheless, the application of these concepts to biological systems is a pristine field. Identification of those nodes that guide the behavior (or evolution) of a network and drive its dynamics would be of great interest in pathologies such as epilepsy.

Classification of Brain Networks

There is now some evidence showing that network metrics are robust enough quantifiers of brain activity to be used as features capable of distinguishing healthy from pathological behavior (Zanin et al. 2012). Ultimately, network theory should help in the identification of the signatures of pathology in a selective way and in the comparison and classification of anatomical and functional networks, thus lending a hand in the early

detection of brain neurodegenerative diseases or in the monitoring of a healthy aging.

Neural Coding

Barry Richmond
Section on Neural Coding and Computation,
Laboratory of Neuropsychology, NIMH/NIH/
DHHS, Bethesda, MD, USA

Definition

Neural coding encapsulates the concept that neurons act as information-processing channels that

take incoming information, integrate it, and produce a signal that contains information encoded in the neuronal (Akil and Lewis 1993) electrical activity pattern.

Detailed Description

The brain can be regarded as an information-processing machine. It takes sensory information from both the external world and our internal state, compares it with stored representations, be they genetically encoded or learned, and produces directed behavior. The basic units for information processing are single neurons. Single neurons act as information channels, taking inputs impinging upon them from other neurons (or sensory organs at the periphery), integrating those inputs, and emitting a response. The step from input to output, both in single neurons and across populations, gives rise to what has been called the neural code, where a code is a signal that carries an abstract representation of some signal or process of interest. For example, neurons in the visual system carry information about some aspect of the visual scene. The code can be directly related to the signal being encoded such as the intensity of the neural response could be directly related to the intensity of the light in the visual scene. In almost all cases, however, the code is not that simply related to the signal being encoded, or if it is, we do not recognize the link. The ultimate goal of studying neural coding is to understand what information is taken in, how it is encoded, and how it is integrated across populations of neurons to give rise to coherent behavior.

The spike train, which is a series of narrow pulses (see ► [“Spike Train”](#)), is a code of great interest because it is the means by which information is transmitted over distances beyond a maximum of a hundred microns or so, and even at short distances, it is often the response of interest. This pulse train arises from sampling the fluctuations across the neuronal cell membrane; whenever the potential reaches a threshold value, a self-propagating pulse, an action potential that travels down the axon, is emitted. When the pulse reaches the axonal terminus, it often leads to the release of

neurotransmitter packets, the number of which is variable from pulse to pulse. These packets in turn influence the membrane potential of the target neuron, making the target more (excitatory) or less likely (inhibitory) to emit a pulse of its own. The sequence of these spikes is related to the pattern of fluctuations in the membrane potentials. In reduced systems such as tissue culture or tissue slice and in invertebrates, the membrane potential can be recorded directly. However, recording the membrane potential itself requires touching the neuron, a procedure so difficult that it can only be done under exceptional circumstances in vertebrates where the brain moves due to pulsations from blood entering and leaving with each heartbeat. Thus, in vertebrates the best look at neural codes is to examine the sequence of spikes. When the set of packets impinging on a target arise from some coherent input signals, for example, a particular visual stimulus, the sequence of spikes that follow can be treated as a code related to the input. Thus, spike trains of encoded information cascade through the nervous system, with the integration of these trains on target neurons giving rise to spike trains representing some complex integration of the incoming signals.

In the cerebral cortex, each neuron is thought to receive inputs from up to 10,000 other neurons, although these may have far different amounts of influence or weight on the targets. Spike trains have a great deal of variability to the point where the individual members in sets of emitted spike trains are seldom if ever identical. One issue of continuing debate is whether to consider the variability as true noise or whether it is unexplained variability with the possibility that it might someday be explained. At this time, if there is an explanation for the variability, it is beyond the resolution of our current techniques to describe in other than statistical terms, so it is in large part treated as noise. As a qualification, there are examples especially in early sensory processing where the variability can be small under conditions of strong, rapidly varying input, that is, when the membrane potential is being jerked quickly and hard.

For investigation of neuronal codes, the sequence of pulses is often considered to arise as a point process, that is, a series of equivalent

impulses without width. In this context the issue is whether the encoded information can be read out from the pattern of pulses. Because of the variability, this becomes a problem in statistical pattern recognition (Richmond 2009). The tools that have been most useful to date come from statistics, information theory, signal processing, and statistical pattern recognition. It is clear from inspection and easily confirmed quantitatively that the number of spikes being emitted encodes information (Optican and Richmond 1987). In general, the number of spikes (see ► [“Estimation of Neuronal Firing Rate”](#)) is the most robust aspect of the neural code.

There are several issues to consider when confronting neural codes. First, the spectrum of information that is encoded must be hypothesized or known – what does the information represent? Second, the representation in the neuronal spike train must be hypothesized – what is the code? Finally, there must be some hypothesis about how the signals are related within the population, that is, what is the population code? Defining the spectrum of information and the code is an interactive process. The experimental conditions are varied, and the neuronal spike train is examined to determine whether there are related changes – these changes are the neural code. For example, in the visual system, changes in the visual scene are related to the changes in the neuron’s activity (Hubel and Wiesel 1962), and in other brain systems such as the orbitofrontal cortex, changes in what is provided as a reward lead to changes in neuronal activity (Kobayashi et al. 2010).

Critical to identifying the neural code is to learn what aspect of the neuronal activity changes, that is, what is the code? It is obvious and universally agreed that the number of spikes changes. For example, for one neuron in the primary visual cortex, presentation of a vertical bar of light might elicit a lot of spikes while the stimulus is on, whereas a horizontal bar will only elicit a few, if any, spikes. In orbitofrontal cortex, delivering grape juice as a reward might elicit a lot of spikes from one neuron and orange juice only a few. Defining the spectrum of stimuli, whether easily parameterized like the orientation of a bar of light or difficult to parameterize like grape vs. orange juice, is referred to as measuring the “tuning.”

If the number of spikes were the only aspect of the response making up the code, understanding the code would reduce to the problem of knowing how long to observe the spike train to get a good estimate of its rate and know how variable it is. This hypothesis is essentially that the response is a fixed stochastic point process, something closely related to a Poisson process (spike trains have never been found to be strictly Poisson). However, again it is easy to observe that the pattern of spikes varies, also. There are two ways to consider the pattern. The first is that the pattern might represent a time-varying underlying signal and that the number of spikes is following that time-varying signal. This hypothesis is that the response is essentially a time-varying point process similar to a time-varying Poisson process. Both of these codes, the rate and the time-varying rate, account for a substantial proportion of the power in neural codes (Wiener and Richmond 2003). The final possibility is that the timing of some or all of the individual spikes is under tighter control than either of the first two possibilities, that is, there are spike patterns at some level of detail, an elegant speculation that arises from theoretical considerations of neural networks as synfire chains (Abeles 1991) (see ► [“Spatial Temporal Spike Pattern Analysis”](#)). This last possibility is under debate. The transmission of such a code presumably requires carefully placed targeting of axons onto target neurons to take advantage of these patterns, something that is hypothesized by some, but difficult to prove (Staude et al. 2008).

Decoding requires a hypothesis about what has been encoded such as the orientation of a bar of light in the primary visual cortex and a guess as to what aspects of the neural responses carry information. Finally, there must be data. Frequently when there is no explicit model of the transformation from input to output, codes are tested using a Bayesian decoder. The experimenter measures the responses to several inputs, say bars of light with different orientations. The joint probability distribution, $p(s, r)$, is calculated. What is to be identified is $p(s|r)$, the posterior probability of each input given the neural response, $p(s|r) = p(s, r)/p(r)$. r can be a vector, allowing estimation of decoding assuming multidimensional response

codes (see ► [“Generalized Linear Models for Point Process Analyses of Neural Spiking Activity”](#)). This procedure, as straightforward as it is theoretically, is fraught with difficulties in practice. Gathering enough examples to estimate the probability functions is difficult, and there is a substantial literature (see ► [“Population Encoding/Decoding”](#)) about how to deal with the problem.

Population codes, which can be conceptualized as multidimensional codes, remain a frontier. The problem for estimation of probability distributions is magnified. To really learn how population codes work will almost certainly require knowing the circuit in detail with the dynamics of how signals pass through groups of neurons. Currently, population codes assume simple averaging of some sort, e.g., the vector codes that scale responses according to the weights on their tuning curves are common (see ► [“Neuronal Population Vector”](#)). Although there have been some quite spectacular results in invertebrates, matching those results in vertebrates seems out of reach, although new techniques such as molecular tools and new high-resolution imaging techniques are likely to improve this situation. So, unfortunately, there is little direct evidence in vertebrates about how encoded signals are combined within populations.

Neural Coding of Speech Sounds

Michael P. Kilgard and Crystal T. Engineer
School of Behavioral and Brain Sciences,
The University of Texas at Dallas, Richardson,
TX, USA

Synonyms

Cortical representation of speech sounds; Distributed speech processing; Neural processing of speech; Neural representation of speech sounds

Definition

Speech sounds are composed of both rapid spectrotemporal changes and slow steady-state portions. The neural coding of speech sounds involves the representation of precise action potential timing across many cortical areas. Behavioral speech sound discrimination accuracy is well predicted by quantifying the similarity between the spatiotemporal response patterns evoked by two sounds.

Detailed Description

Speech Sounds

Speech sounds, like all sounds, evoke patterns of activity in the auditory nerve that are transmitted to the central nervous system. The brain must accurately identify speech sounds despite large amounts of acoustic variability. For example, it is possible to perceive the word “dad” regardless of who is speaking (a male, female, or child), in various types of degradation (at a cocktail party or a concert), or at various intensities (when the sound is whispered or shouted). Speech sounds are incredibly robust and highly redundant. While there are many acoustic cues that can be used to identify an individual sound, no one cue is necessary for sound identification. Voice onset time (VOT) is the amount of time between the onset of a consonant and the onset of voicing. The words “dad” and “tad” differ in their VOT and can often be categorized using this cue alone, but in the absence of this cue, other cues, such as burst intensities, pitch contours, or formant transition durations, can also be used to accurately categorize the two sounds.

Speech sounds are composed of both rapid spectrotemporal changes and slow steady-state portions. Imaging studies performed in humans do not have the level of spectral and temporal precision needed to study speech processing. Because it is rare to have the opportunity to record the responses to speech sounds in human auditory cortex, most speech processing studies are conducted in animals. Numerous studies have

documented the ability of animals to discriminate speech sounds as accurately as humans. Chinchillas can easily categorize words by VOT and have the same category boundary as humans (Kuhl and Miller 1975). In addition to being able to discriminate sounds by VOT, other animal studies have shown that animal performance matches human performance on consonant (Reed et al. 2003; Engineer et al. 2008) and vowel discrimination tasks (Kluender et al. 1987; Perez et al. 2013), speech in noise discrimination tasks (Shetake et al. 2011), and speech discrimination tasks using spectrally and temporally degraded stimuli to simulate cochlear implants (Ranasinghe et al. 2012).

Primary Auditory Cortex Coding of Speech Sounds

Cortical responses to speech sounds in animals resemble the responses to speech sounds recorded in human auditory cortex (Steinschneider et al. 1999, 2005). The acoustic features a speech sound is composed of can be derived from auditory cortex responses (Schreiner et al. 2006; Mesgarani et al. 2008). In both humans and animals, sounds differing in their VOT evoke unique temporal activity patterns. Sounds with a short VOT evoke a single peak of activity in response to the consonant onset, while sounds with a long VOT evoke a second peak of activity in response to the onset of voicing (Steinschneider et al. 2003, 2005; Wong and Schreiner 2003). Likewise, consonants differing in their place of articulation (POA) evoke unique spatial activity patterns. For example, the consonant /b/ evokes the strongest response at low-frequency recording sites, /g/ evokes the strongest response at mid-frequency recording sites, and /d/ evokes the strongest response at high-frequency recording sites (Steinschneider et al. 1995; Engineer et al. 2008).

Although the neural responses reflect differences along single acoustic cue dimensions, these differences do not always correctly reflect how the sound is perceived (Sharma et al. 2000). This suggests that the cortical responses to

multiple acoustic cues need to be integrated in order to accurately identify a sound. The primary auditory cortex spatiotemporal response pattern to speech sounds strongly predicts consonant discrimination performance. Sounds that evoke similar cortical activity patterns (/m/ and /n/) are difficult for rats to discriminate, while sounds that evoke more distinct cortical activity patterns (/d/ and /s/) are easy for rats to discriminate (Engineer et al. 2008). Neural similarity is quantified using Euclidean distance where the ED between the spatiotemporal response pattern to sound x and the spatiotemporal response pattern to sound y is the square root of the sum of the squared differences between the firing rates in each temporal bin (j) at each recording site (i):

$$\text{Euclidean distance} = \sqrt{\sum_{i=1}^{\text{\#sites}} \sum_{j=1}^{\text{\#bins}} (x_{ij} - y_{ij})^2}$$

Neural similarity using the primary auditory cortex spatiotemporal response pattern strongly predicts consonant discrimination performance in quiet, background noise and when the sounds are spectrally or temporally degraded (Engineer et al. 2008; Shetake et al. 2011; Ranasinghe et al. 2012). Consonant discrimination performance is well predicted when the temporal activity pattern is preserved using 1–10 ms bin sizes but is not well predicted when the temporal activity pattern is eliminated. In a primary auditory cortex study of vocalization stimuli, the amount of information present in the neural response pattern remains high with bin sizes less than 40 ms (Schnupp et al. 2006, 2010). Information is quantified using mutual information in bits, where $p(x, y)$ is the joint probability distribution function of x (sound identity) and y (sound classification) and $p(x)$ and $p(y)$ are the marginal probability distribution functions of x and y , respectively:

$$MI = \sum_{xy} p(x, y) \cdot \log_2 \left(\frac{p(x, y)}{p(x) \cdot p(y)} \right)$$

Interestingly, consonant sounds and vowel sounds are not represented on the same timescale in primary auditory cortex. Behavioral

discrimination accuracy of vowel sounds, which are steady-state sounds without rapid transitions, is well predicted when the temporal activity pattern is eliminated but is not well predicted when the temporal activity pattern is preserved (Ranasinghe et al. 2012; Perez et al. 2013). This finding of differential coding of consonants and vowels is consistent with the asymmetric sampling in time (AST) hypothesis that speech sounds are extracted using multiple temporal integration windows (Poeppel 2003). Sparse mathematical representations of speech that minimize the number of active model neurons needed to represent typical speech sounds have receptive fields that are similar to neurons in inferior colliculus, thalamus, and auditory cortex (Carlson et al. 2012).

Non-primary Auditory Cortex Coding of Speech Sounds

Speech sound processing takes place along a hierarchy in auditory cortex. Like the visual system, the auditory system is thought to be divided into separate processing pathways: an anteroventral pathway used to identify a sound and a posterodorsal pathway used for auditory spatial discrimination (Rauschecker and Scott 2009). Neurons in the superior temporal gyrus (STG) and the ventrolateral prefrontal cortex (vPFC), both further along the nonspatial hierarchy compared to primary auditory cortex, accurately identify vocalizations with rapid spectrotemporal transitions when the temporal activity pattern is preserved (Russ et al. 2008). However, pairs of neurons in the vPFC are less redundant (i.e., code more complex or orthogonal properties of a vocalization) compared to pairs of neurons in the STG (Miller and Cohen 2010) and more accurately encode the speech sound category decision than the actual speech sound category (Lee et al. 2009), demonstrating the hierarchical processing between the two areas. Stimulus reconstruction using a nonlinear modulation model and a linear spectrogram model can identify speech sounds using non-primary auditory cortex population responses (Pasley et al. 2012).

Definition

Neural decoding refers to the process of transforming measured neural activity from its original, usually high-dimensional, domain of representation to a new domain that is typically of much lower dimension.

Detailed Description

Overview

In information theory, “decoding” means reversing an “encoding” process that was used to encrypt a set of information-bearing signals in a new domain, usually of lower dimension, where the information is fully preserved. In neuroscience, “encoding” is concerned with the neural representation of behavioral covariates (e.g., sensory inputs, motor outputs, or other cognitive processes). As such, neural decoding is concerned with the process of *off-line* extraction of information about these behavioral covariates from the measured neural activity (Dayan and Abbott 2005; Wallisch et al. 2008).

The definition of neural decoding, however, has evolved since the introduction of neuromotor prosthesis (NMP) in which neural activity is measured and instantaneously used, through neural decoders, to effect the state of an external device (Fetz 1969; Chapin et al. 1999; Serruya et al. 2002; Taylor et al. 2002). Because the state of that device becomes observable to the subject who modulates the neural activity, changes in the encoding process as the subject learns to control the device become quite significant. Neural decoding in such setting refers to the *online* transformation of the measured neural activity. Consequently, a critical difference between online and off-line neural decoders is that the former has to deal with continuously varying representation of information in the neural activity based on the user’s motor intent within the NMP context, whereas the latter does not.

Because neural decoders are critical to NMP performance, a large body of studies has been devoted to explore ways to optimize their design. Historically, neural decoders were derived through a mathematical inversion of some “encoding model” of movement variables such as directional tuning (Schwartz et al. 2001). More recently, it was demonstrated that arbitrary mathematical mappings can also act as neural decoders, effectively creating a novel way to

engage learning and adaptation by the subject (Fetz 2007; Orsborn and Carmena 2013).

Electrical neural activity from a wide range of signals can be used for decoding. Depending on the level of invasiveness, electroencephalograms (EEGs), electrocorticograms (ECoGs), and extracellular recordings of action potentials (APs) and local field potentials (LFPs) have been used as signal sources in NMP applications. Nonelectrical sources can also be used, such as functional magnetic resonance imaging and functional near-infrared spectroscopy, though portability, affordability, and practicality are major impediments to using such signal modalities (Thakor 2013). As such, we focus here on online neural decoding algorithms that make use of extracellular recordings. These algorithms are also applicable to minimally invasive (ECoGs) and noninvasive (EEG) decoding as well as to decoding signals from the peripheral nervous system such as electromyograms (EMGs).

We first provide a brief overview of the types of signals and features used in decoding, then we follow by a description of the most commonly used online decoding algorithms. While these algorithms have been used for both off-line and online decoding, the emphasis is on the online decoding aspects. We conclude with a discussion of further algorithmic innovations that pertain to online closed-loop decoding.

Extracellular Recordings

Spikes, the most common term for AP waveforms, and LFPs can be acquired using microelectrodes implanted in close proximity to individual neurons or clusters of cell bodies (Nicollelis 2001; Dayan and Abbott 2005; Buzsáki 2004). This includes single-unit activity (SUA) and multi-unit activity (MUA) – the aggregate activity of a small group of neurons (Schwartz 2004; Millán and Carmena 2010; Becedas 2012). Based on off-line neural decoding studies, these signals usually contain affluent information about movement parameters, such as direction, velocity, acceleration, among others (Georgopoulos et al. 1986; Schwartz et al. 1988, 2001; Schwartz 2004). As such, they are also believed to contain similar information during online decoding. One caveat

of using these signals in online decoders is that the process of implanting penetrating electrodes in the brain usually elicits neuroprotective mechanisms that result in gliosis with subsequent degradation in signal quality. On the other hand, LFP signal quality often persists over longer periods of time compared to spikes in chronic implants (Becedas 2012; Lee et al. 2013; Flint et al. 2013).

Spike Times and Firing Rates

It is critical to derive continuous-time signals for online neural decoders to ensure smooth control of the actuated device. As such, neuronal APs are first extracted from extracellular recordings by high-pass filtering above 300 Hz, where such signals typically exist in the high-frequency band of 300–6000 Hz (Brockmeier and Príncipe 2013). A sequence of occurrences of APs can be simply characterized by a list of spike times, i.e., a *spike train*. Spike trains can then be mathematically represented as infinitesimally narrow spikes idealized in the form of Dirac δ functions (Dayan and Abbott 2005):

$$\rho(t) = \sum_{i=1}^n \delta(t - t_i) \quad (1)$$

Spike counts from SUA or MUA are then calculated as the integration of spike trains in time windows (bins) of a predetermined width Δ . These spike counts are approximate estimates of the firing rates in the specified time bins (Dayan and Abbott 2005), up to a scaling factor of Δ , as

$$r[k] = \frac{1}{\Delta} \int_{(k-1)\Delta}^{k\Delta} \rho(\tau) d\tau \quad (2)$$

In practice, the scaling factor $\frac{1}{\Delta}$ can be dropped with proper rescaling of the decoder coefficients, and the firing rate estimates are commonly known as binned spike counts. The discrete-time signal $r[k]$ is derived from a continuous-time signal $\rho(t)$ with a sampling period of Δ . However, the use of rectangular (boxcar) window in binned spike counts usually results in noisy estimates of instantaneous firing rates $r[k]$. As such, a smoothing window (kernel) is sometimes used to estimate the instantaneous firing rates (Brockmeier and Príncipe 2013).

Local Field Potentials

Unlike SUA, LFPs represent an aggregate sum of neuronal activity of hundreds to thousands of cells within the vicinity of the recording electrode tip (Andersen et al. 2004; Buzsáki et al. 2012; Lee et al. 2013). LFPs are in the lower frequency band (0.5–300 Hz) of extracellular recordings (Brockmeier and Príncipe 2013). LFPs can be separately used in online decoding, or in combination with SUA, for neural decoding with comparable or better performance to SUA. Recent work has shown that better decoding performance may result compared to only SUA decoding (Andersen et al. 2004; Lee et al. 2013). Signal powers in different frequency bands in the LFP (e.g., beta, 13–30 Hz, and gamma, 30–70 Hz) have been typically used as features for decoding.

Continuous Decoding Approaches

In continuous decoding, a control signal is decoded from neural activity at progressive time samples, thereby forming a decoded “trajectory.” Since the features being decoded vary continuously over time, system identification methods can be used to identify the relationship between the inputs and the outputs (Brockmeier and Príncipe 2013).

Continuous decoding has been used to estimate kinematic and kinetic parameters from cortical

extracellular recordings in NMPs (Hatsopoulos and Donoghue 2009; Homer et al. 2013).

Linear Decoding

Linear decoding assumes a linear transformation between the features extracted from neural activity and the output control signal (e.g., velocity of the actuated device). Despite its simplicity, linear decoding has been proven to be very useful both in online and off-line decoding contexts and is one of the most commonly used decoding approaches in NMPs (Schwartz et al. 2001; Homer et al. 2013). Linear decoding involves linear regression and its commonly used extensions.

Linear Regression Without loss of generality, the input to the decoder is assumed to be the discrete-time signal $r[k]$ that represents estimated neuronal firing rates (following the definition in Eq. 2). Let $\{r_i[k]\}_{i=1,\dots,C}$ denote the instantaneous firing rates of C neurons being decoded. The decoded output can be expressed as (Bishop 2006)

$$v[k] = w_0 + w_1 \cdot r_1[k] + \dots + w_C \cdot r_C[k] \quad (3)$$

For decoding multiple time bins $k = 0, \dots, T-1$, we use the matrix form

$$\begin{bmatrix} v[0] \\ v[1] \\ \vdots \\ v[T-1] \end{bmatrix}_{T \times 1} = \begin{bmatrix} 1 & r_1[0] & r_2[0] & \dots & r_C[0] \\ 1 & r_1[1] & r_2[1] & \dots & r_C[1] \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & r_1[T-1] & r_2[T-1] & \dots & r_C[T-1] \end{bmatrix}_{T \times C+1} \begin{bmatrix} w_0 \\ w_1 \\ w_2 \\ w_3 \\ \vdots \\ w_C \end{bmatrix}_{C+1 \times 1} \quad (4)$$

If we assume that both the input $r[k]$ and the output $v[k]$ are zero centered, then the bias weight w_0 and the extra column of ones can be eliminated, and we can write

$$\mathbf{y} = \mathbf{R} \times \mathbf{w} \quad (5)$$

where $\mathbf{v} \in \mathbb{R}^T$ is the vector of output samples, $\mathbf{R} \in \mathbb{R}^{T \times C}$ is a matrix with entries from zero-

centered neuronal firing rates, and $\mathbf{w} \in \mathbb{R}^C$ is a vector of decoder coefficients (weights). Zero-centering of the neuronal firing rates can be done by subtracting the average (baseline) firing rate for each neuron.

In the biomimetic approach to neural decoding, a set of input samples (e.g., neural firing rates) and output samples (e.g., kinematics) are typically

measured during a decoder training session where subjects passively observe the action to be performed, or imagine making movements with their limbs (Hatsopoulos and Donoghue 2009). In the current linear regression problem, the vector of decoder coefficients $\mathbf{w}^*$ that minimizes the squared error $\|\mathbf{v} - \mathbf{R} \times \mathbf{w}^*\|^2$ satisfies the *normal equation*

$$\mathbf{R}^T \mathbf{R} \times \mathbf{W}^* = \mathbf{R}^T \times \mathbf{V} \quad (6)$$

which gives

$$\mathbf{w}^* = (\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T \times \mathbf{V} \quad (7)$$

where $\mathbf{R}^\dagger = (\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T$ is known as the Moore–Penrose pseudo-inverse of the matrix $\mathbf{R}$, and the solution $\mathbf{w}^*$ is known as the *least-squares* solution (Bishop 2006).

Once the decoder coefficients are calculated from the *training set*, the linear regression decoder can be used online by applying Eq. 4 at each time bin k .

Population Vector Algorithm The population vector algorithm (PVA) was developed in the 1980s by Georgopoulos et al. using multiple single-cell recording sessions in monkeys performing a center-out reach task (Georgopoulos et al. 1986; Schwartz et al. 1988). The idea is to represent movement kinematics at every time bin as a 3-dimensional velocity vector $\mathbf{v}[k] = [v_x[k], v_y[k], v_z[k]]^T$, where the vector $\mathbf{v}[k] \in \mathbb{R}^3$ is of unit length, i.e., $\|\mathbf{v}[k]\| = 1$. This velocity vector always points in the current direction of movement. As such, the PVA assumes an *encoding model* of neural firing that linearly correlates with the direction of movement (Schwartz et al. 2001; Schwartz 2004). This model is a linear (cosine tuning) regression model (compare to Eq. 4) for the neural firing rates, namely,

$$r_i[k] - b_i = s_i (p_{xi} v_x[k] + p_{yi} v_y[k] + p_{zi} v_z[k]) \quad (8)$$

which can be written as an inner product between two unit vectors $\mathbf{v}[k]$ and $\mathbf{p}_i = [p_{xi}, p_{yi}, p_{zi}]^T$ as

$$\begin{aligned} r_i[k] - b_i &= s_i \times \mathbf{p}_i \cdot \mathbf{v}[k] \\ &= s_i \times \cos(\theta_{p_i - v_k}) \end{aligned}$$

where b_i is the baseline neural firing rate, s_i is the standard deviation of the SUA firing rate that scales the unit velocity vector $\mathbf{v}[k]$, and $\theta_{p_i - v_k}$ is the angle between the current unit velocity vector $\mathbf{v}[k]$ and the neuron's *preferred direction* $\mathbf{p}_i$. As can be seen, the model assumes a static preferred direction for each neuron at which the neuron fires maximally, i.e., when $\mathbf{v}[k]$ points in the same direction as $\mathbf{p}_i$, the angle between them is *zero* and the neuron fires maximally at a rate of $r_i[k] = b_i + s_i$. On the other hand, when the current movement direction, $\mathbf{v}[k]$, is opposite to the neuron's preferred direction, the neuron fires minimally (below its baseline) at a rate of $r_i[k] = b_i - s_i$, with a saturation at $r_i[k] = 0$ if $b_i < s_i$ (Georgopoulos et al. 1986). Both $\mathbf{v}[k]$, $\mathbf{p}_i \in \mathbb{R}^d$, where $d = 3$ in the current formulation (3-D space). However, the PVA can be extended to some arbitrary dimension d .

Using this encoding model, the PVA can *decode* movement direction from population firing rates $\{r_i[k]\}$ $i = 1, \dots, C$ using a *voting* scheme where each neuron votes according to its preferred direction with some weight w_i :

$$\mathbf{v}[k] = \sum_{i=1}^C w_i \mathbf{p}_i \quad (9)$$

where different weighting formulae have been explored (Schwartz et al. 2001; Georgopoulos et al. 1988). One such formula is

$$\frac{r_i[k] - b_i}{s_i} \quad (10)$$

In matrix form

$$\begin{aligned} &[v_x[k] v_y[k] v_z[k]] \\ &= \begin{bmatrix} \frac{r_1[k] - b_1}{s_1} & \dots & \frac{r_c[k] - b_c}{s_c} \end{bmatrix} \begin{bmatrix} p_{x1} & p_{y1} & p_{z1} \\ \vdots & \vdots & \vdots \\ p_{xc} & p_{yc} & p_{zc} \end{bmatrix} \end{aligned} \quad (11)$$

and by transposing

$$\mathbf{v}[k] = \mathbf{P}^T \mathbf{q}[k], \quad (12)$$

where $q_i[k] = \frac{r_i[k] - b_i}{s_i}$ are normalized firing rates.

Comparing this formulation to Eq. 3, we see that neural decoding using PVA assumes a linear regression model between the input firing rates and output velocity vectors. Further, PVA normalizes the firing rates to mean zero and variance one (where the parameter s_j would be equal to the standard deviation of the neuron's firing rate).

Unlike standard linear regression, PVA does not fit the model parameters $[p_{xi}, p_{yi}, p_{zi}, s_j, b_i]^T$ using the *normal equation*. Instead, PVA uses multiple linear regression analysis to fit these parameters using a linear encoding model (Schwartz et al. 1988).

Optimal Linear Estimator The PVA approach to neural decoding makes strong assumptions about the nature of encoding by primary motor cortex neurons (cosine tuned) and their preferred directions (uniformly distributed). Under these assumptions, the encoding model of the PVA is equivalent to a least-squares (also known as maximum likelihood) estimation (Schwartz et al. 2001). In practice, however, the uniform (spherical) distribution of preferred directions is rarely encountered, and the quality of tuning can vary greatly within the measured sample (Schwartz et al. 2001), particularly when recruitment properties differ when an entire ensemble, rather than an individual cell, is used in the decoder design.

Optimal linear estimator (OLE) models overcome these limitations by defining the neuron's preferred direction as the "center of mass" of the tuning function (Salinas and Abbott 1994).

OLEs find the decoder output $\mathbf{v}[k]$ as the least-squares estimator with minimum variance: (Koyama et al. 2010)

$$\mathbf{v}[k] = (\mathbf{P}^T \mathbf{P})^{-1} \mathbf{P}^T \mathbf{q}[k], \quad (13)$$

Under the assumption that the preferred directions are uniformly distributed within a unit sphere, $\mathbf{P}^T \mathbf{P}$ would be a diagonal matrix and OLE will reduce to PVA (Koyama et al. 2010; Brockmeier and Príncipe 2013). (Compare to Eq. 12.)

In the presence of correlations in the neural firing rates $\mathbf{q}[k]$ – which is often the case – OLEs are given by a weighted least-squares solution, where the inverse covariance matrix Σ^{-1} of the neural firing rates is used as the weights matrix (Koyama et al. 2010; Brockmeier and Príncipe 2013):

$$\mathbf{v}[k] = (\mathbf{P}^T \Sigma^{-1} \mathbf{P})^{-1} \mathbf{P}^T \Sigma^{-1} \mathbf{q}[k]. \quad (14)$$

In online decoding, Δ is typically chosen between 0.01 and 0.1 s, and the estimated firing rates $r_i[k]$ are typically noisy. PVA and OLE require a preprocessing step to smooth these firing rate "trajectories" using a rectangular (boxcar) window (Koyama et al. 2010). Additionally, the time lag between natural arm movement and the neural activity of about 150–200 ms needs to be estimated by optimizing some objective function to ensure the firing rates can be optimally combined (Moran and Schwartz 1999; Koyama et al. 2010).

Wiener Filters A limitation of PVA and OLE is that they do not take into account the characteristics of a changing noise variance. Some elements of this noise may be correlated with the signal (e.g., neural noise), while others may not (e.g., instrumentation noise). A Wiener filter provides an optimal solution to this problem, both off-line (Warland et al. 1997) and online (Paninski et al. 2004; Hochberg et al. 2006). It is equivalent to the linear regression formulation in Eq. 3 but extends to N time lags in the past. As such it includes a history of neural firing, where N is the length of a single-neuron filter, i.e., (assuming zero-centered inputs and output)

$$\begin{aligned} v[k] = & \sum_{j=k-N+1}^k \\ & \times \sum_{i=1}^C r_i[j] w_i[j - k + N - 1] \end{aligned} \quad (15)$$

In matrix form

$$\begin{bmatrix} v[N-1] \\ v[N] \\ \vdots \\ v[T-1] \end{bmatrix} = \begin{bmatrix} r_1[0] & \cdots & r_1[N-1] & \cdots & r_c[0] & \cdots & r_c[N-1] \\ r_1[1] & \cdots & r_1[N] & \cdots & r_c[1] & \cdots & r_c[N] \\ \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ r_1[T-N] & \cdots & r_1[T-1] & \cdots & r_c[T-N] & \cdots & r_c[T-1] \end{bmatrix} \begin{bmatrix} w_1[0] \\ \vdots \\ w_1[N-1] \\ w_2[0] \\ \vdots \\ w_2[N-1] \\ \vdots \\ w_c[0] \\ \vdots \\ w_c[N-1] \end{bmatrix}, \quad (16)$$

e.g.,

$$\mathbf{y} = \mathbf{R} \times \mathbf{w} \quad (17)$$

where $\mathbf{v} \in \mathbb{R}^{T-N+1}$ is the vector of output samples, $\mathbf{R} \in \mathbb{R}^{(T-N+1) \times NC}$ is a matrix with entries from zero-centered neuronal firing rates, and $\mathbf{w} \in \mathbb{R}^{NC}$ is a vector of decoder coefficients (weights). Zero-centering of the neuronal firing rates can be done by subtracting the average (baseline) firing rate for each neuron. Analogous to linear regression, the optimal decoder coefficients can be found by solving the normal equation using the pseudo-inverse of the neural response matrix $\mathbf{R}$ (Warland et al. 1997; Paninski et al. 2004):

$$\mathbf{w}^* = \mathbf{R}^\dagger \mathbf{v} = (\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T \mathbf{v} \quad (18)$$

Despite the fact that both PVA/OLE and Wiener filtering give rise to the same matrix equation for decoding, namely, $\mathbf{v} = \mathbf{R} \times \mathbf{w}$, it should be noted that there exist two fundamental differences between the two approaches:

1. PVA/OLE assumes an explicit encoding model. This model is fit to the training data first, and then a decoder is derived essentially by inverting the encoding model (Koyama

et al. 2010). In contrast, the Wiener decoder is fit directly to the training data (Warland et al. 1997; Paninski et al. 2004).

2. PVA/OLE relates the inputs to the outputs at a single time lag. The noisy decoded output that results from this approach is remedied by averaging the input samples over multiple lags (Koyama et al. 2010). This averaging (filtering) operation is implicit, whereas it is explicit in the Wiener approach, allowing the latter to take the temporal characteristics of the input signals into account (Schwartz et al. 2001). In essence, decoders that take account for correlation dynamics may be exploiting some inherent temporal coding strategies used by the brain (Andersen et al. 2010).

Ridge Regression Ridge regression is commonly used with linear decoding (PVA/OLE and Wiener filtering) of both SUA/MUA and LFPs (Suminski et al. 2010; Flint et al. 2012; Collinger et al. 2013; Flint et al. 2013). It overcomes the limitation of the pseudo-inverse solution to the normal equation, where the pseudo-inverse solution would typically overfit the noise inherent in the data yielding poorer generalization performance (Bishop 2006). Ridge regression introduces a *regularization parameter*, λ , which trades off the bias

and the variance of linear estimators (Marquardt 1970; Bishop 2006). This is a remedy for the case when the matrix $\mathbf{R}^T \mathbf{R}$ is ill conditioned, due to linear correlations between the inputs, in which case finding the inverse of this matrix becomes problematic (Marquardt 1970).

The ridge regression solution is given by

$$\mathbf{w}^* = (\mathbf{R}^T \mathbf{R} + \lambda \mathbf{I})^{-1} \mathbf{R}^T \mathbf{v}, \quad (19)$$

where $\mathbf{I}$ is identity matrix of appropriate dimensions.

Recursive Bayesian Decoding

Linear filters and OLEs, as solutions to the normal equations, bear a probabilistic interpretation: they are maximum likelihood linear estimators under a stationary Gaussian noise model (Bishop 2006). Recursive Bayesian decoders go a few steps further by assuming a *trajectory model* for the decoded output as it relates to the neural activity through a probabilistic *observation model* (Yu et al. 2010). This enables this class of decoders to incorporate two important features: time varying and stochastic behavior of the input and output variables.

The most commonly used recursive Bayesian decoder is the Kalman filter (Wu et al. 2006; Yu et al. 2010). The Kalman filter assumes the decoder output kinematics $\mathbf{x}[k] \in \mathbb{R}^d$ (which can include, e.g., position, velocity, and acceleration) evolve according to a trajectory model

$$\mathbf{x}[k+1] = \mathbf{A}\mathbf{x}[k] + \mathbf{w}[k] \quad (20)$$

where $\mathbf{w}[k] \sim \mathcal{N}(0, \mathbf{W})$ is the Gaussian noise term with the covariance matrix $\mathbf{W} \in \mathbb{R}^{d \times d}$. This model is equivalent to a linear Gaussian model (Wu et al. 2006; Yu et al. 2010):

$$\mathbf{x}[k] | \mathbf{x}[k-1] \sim \mathcal{N}(\mathbf{A}\mathbf{x}[k-1], \mathbf{W}). \quad (21)$$

The observation model is given by

$$r[k] = \mathbf{C}\mathbf{x}[k] + \mathbf{q}[k] \quad (22)$$

where $\mathbf{r}[k] \in \mathbb{R}^C$ is the vector of instantaneous firing rates for the ensemble of neurons, $\mathbf{C} \in \mathbb{R}^{C \times d}$ is a linear encoding model that relates firing rates to kinematics (compare to Eq. 8), and $\mathbf{q}[k] \sim \mathcal{N}(0, \mathbf{Q})$ is the Gaussian noise term with covariance matrix $\mathbf{Q} \in \mathbb{R}^{C \times C}$. This is also equivalent to a linear Gaussian model (Wu et al. 2006; Yu et al. 2010)

$$\mathbf{r}[k] | \mathbf{x}[k] \sim \mathcal{N}(\mathbf{C}\mathbf{x}[k], \mathbf{Q}) \quad (23)$$

Given a training data set with synchronized kinematic and neural data, the parameters of the Kalman filters (covariance matrices, priors, and linear matrices) can be fit to the data using a maximum likelihood approach (see Maximum Likelihood under section “Discrete Decoding Approaches”). Additionally, the optimum time lags between $\mathbf{r}[k]$ and $\mathbf{x}[k]$ can be estimated (Wu et al. 2006).

Given a trajectory model (Eq. 20) and an observation model (Eq. 22), the Kalman filter is an optimal state observer (i.e., it can optimally estimate the kinematic state from the observed firing rates) that minimizes the mean-squared reconstruction error $\sum_{k=0}^{T-1} \|\hat{\mathbf{x}}[k] - \mathbf{x}[k]\|_2^2$ (Wu et al. 2006). The Kalman filter algorithm is a recursive algorithm that implements the following steps:

1. Given the last state estimate $\hat{\mathbf{x}}[k-1]$, use the trajectory model to predict the current state estimate

$$\hat{\mathbf{x}}_-[k] = \mathbf{A}\hat{\mathbf{x}}[k-1] \quad (24)$$

2. Compute the increase in uncertainty over the state, expressed by the error covariance matrix:

$$\mathbf{V}_-[k] = \mathbf{A}\mathbf{V}[k-1]\mathbf{A}^T + \mathbf{W} \quad (25)$$

3. Use the observation model to calculate a prediction of the firing rates which should be $\hat{\mathbf{r}}[k] = \mathbf{C}\hat{\mathbf{x}}_-[k]$. Compare this prediction to the actual firing rates $\mathbf{r}[k]$, and use the difference to update the current state estimate through the *Kalman gain* $\mathbf{K}[k]$:

$$\hat{\mathbf{x}}[k] = \hat{\mathbf{x}}_-[k] + \mathbf{K}[k](\mathbf{r}[k] - \hat{\mathbf{r}}[k]) \quad (26)$$

$$\mathbf{K}[k] = \mathbf{V}_-[k]\mathbf{C}^T(\mathbf{C}\mathbf{V}_-[k]\mathbf{C}^T + \mathbf{Q})^{-1} \quad (27)$$

4. Finally, update the uncertainty over the current state by updating

$$\mathbf{V}[k] = (\mathbf{I} - \mathbf{K}[k]\mathbf{C})\mathbf{V}_-[k] \quad (28)$$

Comparing the Kalman filter implementation to the linear filter, it can be seen that:

1. The Kalman filter is recursive, which means it takes into account *all* past neural activity (with decaying exponential weights) rather than just N lags (Wu et al. 2006; Yu et al. 2010).
2. The uncertainty about each state estimate is given in the form of error covariance matrices at each time step, from which one can draw confidence intervals (Bishop 2006; Yu et al. 2010).

The Kalman filter assumes a parametric model. Another popular recursive Bayesian decoder that is nonparametric is the *particle filtering* approach (Brockwell et al. 2004). The parameterization is traded off with added computational expense in the latter approach.

Nonlinear Decoding

Artificial Neural Networks Artificial neural networks have origins in the early attempts to mathematically represent the computational aspects of biological systems. Their power comes from their ability to model arbitrary nonlinear mappings. They can be used for continuous decoding (i.e., regression) as well as for discrete decoding (i.e., classification – see section “[Discrete Decoding Approaches](#)” below) (Bishop 2006). They have been used for real-time prediction of hand trajectories from neural ensembles in M1 (Wessberg et al. 2000). The three Cartesian coordinates were assumed to be independent each with a separate output layer. The network outputs were successfully used to drive a robotic hand.

Volterra Series Volterra series is a nonlinear nonparametric model that is frequently used in system identification. It is the generalization of Taylor series to systems with memory, where the output of the nonlinear system can depend on the input at all previous time lags (Paiva et al. 2010; Song and Berger 2010).

A model with parametric and nonparametric components was developed for hippocampal prostheses. The overall model structure is parameterized to be “neuron-like,” while the input–output relationships of the model subcomponents are captured with the nonparametric Volterra series. This model is a neural decoder that transforms input neural signals from one brain region into output signals that activate another nervous system region (Hsiao et al. 2013). It has been successfully applied to predict the hippocampal CA3-CA1 population dynamics (Berger et al. 2005; Song and Berger 2010).

Discrete Decoding Approaches

Discrete decoding is used in applications in which knowledge of discrete end effector states is needed. A typical example is communication prostheses, in which subjects are instructed to choose between two or more discrete targets, with examples ranging from a simple click/no-click choice to spelling entire words. In this regard, communication prostheses are more concerned with “information throughput” from the subject to the outside world. One important distinction between continuous decoding and discrete decoding is that in the latter a target can be immediately chosen once it is decoded from neural activity, without the need to follow a specific trajectory to reach that target. For example, in spelling applications, the spatial locations of letters displayed on a screen keyboard that the user intends to strike are decoded, and a cursor is instantaneously moved to strike that letter. In this context, multiple classification techniques from pattern recognition are successfully used based on neural activity recorded during motor planning (Yu et al. 2010; McFarland and Wolpaw 2011; Gilja et al. 2011). Discrete decoding, however, is

not limited to communication prostheses applications. Indeed, a grasp/no-grasp state decoder was utilized in NMPs for people with tetraplegia (Hochberg et al. 2012), and it was shown that NMPs can benefit from discrete decoders whenever the “intended target(s)” can be decoded efficiently in goal-directed movements (Yu et al. 2010; Shanechi et al. 2012).

Linear Discriminant Analysis Linear discriminant analysis (LDA) is an approach to discrete classification of measured variables. LDA, particularly Fisher’s linear discriminant, is one of the most popular approaches to discrete neural decoding, specially in the noninvasive brain–computer interfaces (McFarland and Wolpaw 2011) as well as peripheral neural interfaces (Micera et al. 2010). LDA utilizes *discriminant functions* for decoding, where a discriminant function is a function that takes an input vector $\mathbf{r}$ and assigns it to one of K classes directly. A linear discriminant makes use of a linear function: $y_k(\mathbf{r}) = \mathbf{w}_k^T \mathbf{r}$, such that class k is chosen for input $\mathbf{r}$ if $y_k(\mathbf{r}) \geq 0$ (assuming no bias) (Bishop 2006).

Briefly, Fisher’s linear discriminant is defined in terms of a projection onto a lower dimensional subspace. For a simple two-class problem (Bishop 2006), let the input vectors $\mathbf{r}_i, i = 1, \dots, N_1$ be members of class C_1 and the input vectors $\mathbf{r}_i, i = 1, \dots, N_2$ be members of class C_2 , where $\mathbf{r}_i \in \mathbb{R}^D$. Let the means of the vectors belonging to both classes be $\mathbf{m}_1$ and $\mathbf{m}_2$, respectively. Let $\mathbf{w}$ be a vector that projects the input vectors, and their means, to a one-dimensional subspace (a line). The D -dimensional means $\mathbf{m}_1$ and $\mathbf{m}_2$ are projected to the points m_1 and m_2 , respectively. Choosing a unit vector $\mathbf{w}$ to maximize the *separation* between the projected means, $|m_1 - m_2|$, allows separating the projected vectors from the two classes using a simple threshold in the one-dimensional subspace. The choice of $\mathbf{w}$ corresponds to a vector that is parallel to the vector connecting the two means $\mathbf{m}_1$ and $\mathbf{m}_2$. When features from input vectors are not statistically independent, the classes may significantly overlap in the projection subspace. This overlap can be quantified in terms of the *within-class variance* of the input vectors after projection,

i.e., $s_k^2 = \sum_{i=1}^{N_k} (x_i - m_k)^2$, where $\mathbf{x}_i = \mathbf{W}^T \mathbf{x}_i$ is the projection of an input vector $\mathbf{x}_i$. Fisher’s linear discriminant approach chooses $\mathbf{w}$ such that the ratio of the between-class separability to the within-class variance is maximized. This criterion can be expressed as

$$J = \frac{(m_2 - m_1)^2}{s_1^2 + s_2^2}, \quad (29)$$

which can be written explicitly in terms of the original input vectors and $\mathbf{w}$ as

$$J(\mathbf{w}) = \frac{\mathbf{w}^T \mathbf{S}_B \mathbf{w}}{\mathbf{w}^T \mathbf{S}_W \mathbf{w}}, \quad (30)$$

where $\mathbf{S}_B$ is the *between-class* covariance matrix defined in terms of the means and $\mathbf{S}_W$ is the *within-class* covariance matrix defined as the sum of original input vectors covariance matrices. The optimal projection vector $\mathbf{w}$ that maximizes J is in the same direction as $\mathbf{S}_W^{-1}(\mathbf{m}_2 - \mathbf{m}_1)$. After projecting all input vectors into this low-dimensional subspace, we can discriminate between the classes using simple linear discriminants, which could be a single threshold in case of one-dimensional subspaces. Fisher’s linear discriminant can be generalized to multiple classes (Bishop 2006) and even extended to handle nonlinear decision boundaries using the *kernel trick* (Paiva et al. 2010).

Support Vector Machines Support vector machines (SVM) are also popular in discrete neural decoding (Micera et al. 2010; McFarland and Wolpaw 2011). They can be thought of as *maximum margin classifiers*, where a margin is defined as the smallest distance between the decision boundary and any of the training feature vectors. SVMs can be trained efficiently by solving a quadratic programming problem (i.e., an optimization problem with a quadratic cost function subject to linear constraints). Once trained, the training feature vectors are discarded, except for a few vectors that reside on the maximum margin, known as *support vectors*. Similar to LDA, the *kernel trick* (Paiva et al. 2010) can be used to extend SVMs to handle nonlinear decision boundaries (Bishop 2006).

Maximum Likelihood Two of the most commonly used probabilistic discrete decoding approaches are maximum likelihood (ML) and maximum a posteriori (MAP) classifiers. The link between these two approaches is Bayes' theorem. Let a particular behavioral variable of interest be denoted by s , and the vector of features (e.g., neural firing rates) be denoted by $\mathbf{r}$, then Bayes' theorem relates the probabilities for s and $\mathbf{r}$ as

$$\mathbb{P}(s | \mathbf{r}) = \frac{\mathbb{P}(\mathbf{r} | s)\mathbb{P}(s)}{\mathbb{P}(\mathbf{r})}, \quad (31)$$

where $\mathbb{P}(s)$ is the prior probability of observing a value for s , $\mathbb{P}(\mathbf{r})$ is the probability of observing a feature vector $\mathbf{r}$, $\mathbb{P}(\mathbf{r}|s)$ is the conditional probability of how likely it is to observe the feature vector $\mathbf{r}$ given that a specific value for s was observed for the behavioral variable, and $\mathbb{P}(s|\mathbf{r})$ is the posterior probability of the behavioral variable taking on a value s given the observed feature vector $\mathbf{r}$ (Dayan and Abbott 2005; Quian and Panzeri 2009). In communication prostheses, the variable s is the most likely target (Yu et al. 2010).

The ML approach makes direct use of the *likelihood function* $f(s) := \mathbb{P}(\mathbf{r} | s)$ (Bishop 2006). ML decoders select the value for s that maximizes the likelihood function for the observed feature vector $\mathbf{r}$, i.e.,

$$s_{\text{ML}} := \arg_s \max \mathbb{P}(\mathbf{r} | s) \quad (32)$$

On the other hand, MAP selects the value for s that maximizes the *posterior probability*:

$$s_{\text{MAP}} := \arg_s \max \mathbb{P}(s | \mathbf{r}) \quad (33)$$

As such, when all targets are equally likely, the MAP essentially reduces to the ML (Bishop 2006; Quian and Panzeri 2009).

In both approaches, it is critical to model the probability distributions involved in Bayes' theorem, with the conditionally independent multivariate Gaussian and Poisson models being most commonly used, where conditional independence is assumed between the different variables (components) of $\mathbf{r}$. The conditional independence

assumption is used largely for practical reasons (e.g., to simplify the model and avoid overfitting) (Yu et al. 2010), but it ignores the potentially synergistic information encoded in the spike trains of different neurons (Paiva et al. 2010). The Gaussian distribution is more suited for variables that can take on positive and negative values, while the Poisson distribution more accurately models binned spike counts. It is also possible to square-root transform the binned spike counts and then use a Gaussian model (Yu et al. 2010).

Hidden Markov Models Hidden Markov models (HMMs) are conceptually similar to the state space model assumed by the Kalman filter, with the distinction being that the "states" in the HMMs are discrete valued. As such, the state space model becomes a finite-state machine in which the transition between the finite set of states is governed by the state *transition* probabilities. Similar to the Kalman filter, the "states" are *hidden* and not observed. Instead, an observation model is described by the *emission* probabilities, i.e., the conditional probabilities of observing a particular outcome given that the system is in a particular state (Bishop 2006).

HMMs have been used in noninvasive brain-computer interface and peripheral neural interface applications (Micera et al. 2010; Brockmeier and Principe 2013), as well as to detect neural state transitions in motor cortical prostheses (Kemere et al. 2008).

Online Closed-Loop Decoding

Decoder Initialization

A critical step in all neural decoding methods is decoder initialization. In the biomimetic approach, the initialization is done using a concurrently measured set of neural activity and kinematics during motor imagery or action observation (Hatsopoulos and Donoghue 2009). Recent studies, however, have shown that this is not a stringent requirement, as subjects can learn arbitrary mapping between their volitionally controlled neural activity and variables in the task space (Carmena 2013). The closed-loop nature of online NMPs enables subjects to establish a

causal link between the volitionally controlled neural activity and the change in state of the actuated device through an arbitrary mapping (Orsborn and Carmena 2013). Rooted in the pioneering work of Fetz 1969, this mapping can be used to operantly condition subjects to increase the likelihood of specific firing patterns of recorded neurons when coupled to reward. This arbitrary mapping thus constitutes an unsupervised decoder initialization step that is tailored to the observed population without the need for synchronized behavioral covariates. This approach has been extended to other NMP studies (Moritz et al. 2008; Koralek et al. 2012; Badreldin et al. 2013).

Closed-Loop Decoder Adaptation and Calibration

A critical aspect in neural decoding is the extent to which neural decoders need to be adapted and the time scale over which this adaptation needs to take place. When subjects are trained to use a fixed decoder, the experimenter effectively relegates the learning to the subjects. In some cases, the learning process can saturate, and the control performance may not continue to improve with increasing task demands. As such, closed-loop decoder adaptation (CLDA) algorithms attempt to adaptively change the decoder parameters, using adaptive control algorithms, during closed-loop operation in order to accelerate learning and improve performance. Examples include the recursive least-squares (RLS) adaptation (Gage et al. 2005), the Bayesian parameter updates and Kalman smoother (Li et al. 2011), the ReFIT Kalman filter algorithm (Gilja et al. 2012), the SmoothBatch algorithm (Orsborn et al. 2012), the unsupervised and error-based adaptation (Gürel and Mehring 2012), and the reinforcement learning (Pohlmeyer et al. 2014). While there is no consensus on the best strategy for decoder update rules, some points to consider are to determine the following: (i) the decoder parameters that should adapt, (ii) the adaptation rule, and (iii) the frequency of adaptation. Because the mechanisms by which the brain learns to adapt to a particular

decoder are largely unknown, this subject remains a topic of intensive research (Carmena 2013). A temporary, less optimal solution is to limit decoder adaptation to early blocks of closed-loop trials until performance asymptotes and then fix the decoder for the remainder of the session.

Definition

Neural field models describe the spatiotemporal evolution of mean neural activity in neural populations. The neural population is embedded in a continuous spatial domain (mean-field approximation), while its activity is assumed to be coarse grained in space and time. The spatial “grains” are not visible in the mathematical description, but reflect the physiological interpretation that the field is built by tiny hyper-columns.

The temporal “grain” is also not visible in the equations but results from the interpretation of a temporal average over a short time interval, while the field evolves on a larger time scale. Hence, neural fields describe neural population activity averaged over small spatial and temporal structures.

Detailed Description

Physiological Motivation

To deal with the functional complexity and hierarchy of the brain, it is necessary to find the functional relationships between the network activity based on single neurons and neural population activity on a higher hierarchical level. In the 1960s, Hubel and Wiesel had studied in detail the response properties of single neurons and spatially extended populations in the visual cortex and have found the existence of functional neural columns, i.e., populations, in which neurons respond similarly to external stimuli (Rockland 2010). These so-called hyper-columns (or cortical module or macro-column) represent functional self-organized subunits in the brain resulting from the nonlinear interaction of single neurons (DeFelipe et al. 2012). Several experimental and theoretical studies have revealed the importance of spatially extended neural population dynamics in brain functions (Deco et al. 2008), such as hallucinations in the visual cortex (Bressloff et al. 2002), epilepsy (Milton and Jung 2003), or anesthesia and sleep (Hutt 2011).

Standard Derivation of Model Equations

In order to understand the experimental data obtained in neural populations, a promising approach considers theoretical models that elucidate the importance of physiological properties such as synaptic strength or the topology of the underlying neural network. The class of neural field models provides a powerful mathematical description of neural activity. Their major model components reflect dynamic features of single neurons and their interactions. These features are (1) the nonlinear dynamics of the neuron discharge (action potentials or spikes), (2) the temporal neural response to activity changes (at a

certain time scale), (3) the existence of excitation and inhibition, and (4) the spatial connectivity in the case of neural fields. Additional physiological properties (5) render the model more realistic.

The subsequent paragraphs will sketch these model features in some detail.

Population Firing Rate

Single neurons generate action potentials if their membrane potential exceeds a threshold. In a neural population, the number of neurons that fire in a certain short time interval at a certain time is called the population firing rate P . Since it relates the dendritic activity of the neurons U (as input) to the firing rate (as output), $P(U)$ is also called transfer function. The standard derivation of the transfer function (Amit 1989) considers an ensemble of neurons with different firing thresholds U_{th} and a distribution of membrane potentials $d(U - \bar{U})$ with mean potential $\bar{U}$. Then the number of firing neurons in a short time interval Δt is

$$P(U(t)) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \Theta(U - U_{th}) F(U_{th} - U_{th}) d(U - U(t)) dU dU_{th}$$

where F is the number of neurons in the short time interval Δt with threshold U_{th} that are ready to fire, i.e., which have left their refractory period and would fire if their membrane potential exceeds the threshold. The parameter $\bar{U}_{th}$ is the mean firing threshold in the population and $\Theta(x)$ is the Heaviside function with $\Theta(x) = 0$ for $x < 0$ and $\Theta(x) = 1$ for $x \geq 0$. In general, one can show that unimodal statistical distributions F and d lead to a sigmoidal shape of $P(\bar{U})$. The most typical choice for the transfer function is the logistic function

$$P(\bar{U}(t)) = \frac{S_{ra}}{1 + e^{-c(\bar{U}(t) - \bar{U}_{th})}}$$

with the steepness parameter $c > 0$ that is large for narrow firing threshold distributions F .

Temporal Mean Synaptic Response

The membrane dynamics of a single neuron obeys the differential equation

$$CdV(t)/dt = -g_l(V(t) - E_l) - g_s(t)(V(t) - E_s)$$

assuming a single synaptic receptor with conductance $g(t)$ and reversal potential E . The parameters C , g_l , and E_l are the capacitance, constant conductance, and leakage reversal potential of the membrane, respectively. In the absence of the synaptic receptor, the resting potential of such a membrane is $V_r = E_l$. In the absence of any arriving action potentials at the synapse, $g(t) = 0$, while the synaptic receptor channel opens if an action potential arrives at the synapses leading to a conductance change $g(t) > 0$. Typically, excitatory ionotropic receptors respond with a conductance change slower (~ 5 to 200 ms) than the membrane time scale g_l/C of few milliseconds. Assuming this time-scale separation, voltage changes induced by arriving action potentials (so-called postsynaptic potentials, PSPs) decay fast to the resting potential V_r and hence $V(t) \approx E$ on the larger time scale of synaptic receptor response. Following this line of argumentation, the membrane current induced by arriving action potentials at synaptic receptors is $I_s(t) \approx g_s(t)(V_r - E)$.

Now considering a large number of receptors on a single neuron and a large number of neurons, the induced mean synaptic current of a specific receptor type in a population is $\bar{I}(t) \sim h(t)$ where the function $h(t)$ resembles in shape the temporal response function $g(t)$ but taking into account average time scales. These time scales reflect both the heterogeneity of time scales of single receptors and the propagation delay time of PSP along the dendritic tree to the neuron soma. Hence, there is no precise derivation of the mean dendritic response function in the neural mass models but an approximative description based on the single-receptor response. A typical response functions has the bi-exponential form

$$h_2(t) = \frac{\alpha_1 \alpha_2}{\alpha_2 - \alpha_1} (e^{-\alpha_1 t} - e^{-\alpha_2 t}) \Theta(t), \quad \alpha_2 > \alpha_1$$

with the Heaviside function $\Theta(t)$. The parameters α_2 and α_1 are the rise and decay rate of the response function, respectively. For $\alpha_2 = \alpha_1 = \alpha$, one obtains Rall's alpha function $h_2(t) = \alpha t e^{-\alpha t}$. A simple but still physiologically reasonable

model function has the exponential form $h_1(t) = \alpha e^{-\alpha t} \Theta(t)$ which assumes an instantaneous rise and considers the decay phase with time constant $1/\alpha$ only. Now considering the response of neurons in a population to incoming action potentials, the extracellular potential in the population reads

$$\begin{aligned} U(t) &= a \sum_{i=1}^T s_i \int_{-\infty}^t h(t - \tau) \delta(\tau - \tau_i) d\tau \\ &= a \int_0^\infty h(\tau) s(t - \tau) d\tau \end{aligned}$$

where a is the synaptic strength, the action potentials are approximated by delta-function-shaped spikes, τ_i are the spike arrival times at the receptors, s_i are the synaptic weights of the spikes, T is the number of spikes arrived until time t , and $s(t) = \sum_i s_i \delta(t - t_i)$ is the population spike train. Then averaging over a short time interval Δt of few milliseconds, the mean population potential reads

$$\bar{U} = \int_0^\infty h(\tau) P(t - \tau) d\tau$$

where $P(t) = \int_t^{t+\Delta t} s(\tau) d\tau / \Delta t = n(t) / \Delta t$ is the number of incoming spikes in the population in the time interval Δt , i.e., the time-dependent population firing rate.

In most studies, the latter expressions are rewritten as

$$\begin{aligned} \bar{U} &= \int_0^\infty h_{1,2}(\tau) P(t - \tau) d\tau \leftrightarrow \hat{L}_{1,2}(d/dt) \bar{U}(t) \\ &= P(t) \end{aligned}$$

with

$$\begin{aligned} \hat{L}_2 &= \frac{1}{\alpha_1 \alpha_2 dt^2} \frac{d^2}{dt^2} + \left(\frac{1}{\alpha_1} + \frac{1}{\alpha_2} \right) \frac{d}{dt} + 1, \hat{L}_1 \\ &= \frac{1}{\alpha} \frac{d}{dt} + 1 \end{aligned}$$

for the bi-exponential function and exponential function $h_{1,2}(t)$, respectively (Fig. 1).

Neural Field Model, Continuum, Fig. 1 The model postsynaptic potential for two approximations of receptor dynamics

Excitation and Inhibition

Different types of synapses respond differently to incoming action potentials. The most important ionotropic synaptic receptors respond by excitatory (glutamate receptors) and inhibitory (GABA receptors) PSPs. In addition, these synaptic receptors may be axonal terminals of different neuron types, such as pyramidal cells or interneurons. Since both pyramidal cells and interneurons may excite or inhibit postsynaptic neurons, various combinations of cells and synapses are realistic. A typical way to implement synaptic excitation and inhibition is through their sum of their dendritic activity, i.e., the mean dendritic membrane potential that generates the action potential if exceeding a threshold is $U(t) = U_e(t) - U_i(t)$ where the mean excitatory and inhibitory PSP $U_e(t)$ and U_i obey the response dynamics given in the previous paragraph on section “Temporal Mean Synaptic Response”.

Spatial Connectivity

Axonal fiber branches connect neurons, and their spatial range may be short in connections in the same neural structure and long in connections between different neural structures. In addition, short-range axonal branches may project different neuron types onto excitatory and inhibitory

synapses, whereas most long-range axonal fibers originate from excitatory neurons and excite far-distant postsynaptic neurons. Various types of these different connections may be present in the same neural structure, and their combination results in diverse spatial topologies of excitation and inhibition. Neural fields extend point-like neural mass models by a spatial dimension, i.e., $\bar{U}(t) \rightarrow \bar{U}(x, t)$, with spatial location $x \in \Omega$ and hence embed the neural population in the spatial domain Ω . This extension allows one to model spatially extended neural populations as found in real neural tissue.

Mathematically, the spatial interaction is taken into account by an integral over the space of the population introducing a spatial interaction kernel $K(x, y) = \sum_j a_j K_j(x, y)$. The summand K_j is the

probability density function for finding axonal connections of type j between neurons in the hyper-columns at spatial locations x and y , and a_j are weights of the different interactions. The connection type may be excitatory or inhibitory.

If the connectivity in the neural field just depends on the distance between two spatial locations and hence is independent of the spatial location itself, i.e., $K_j(x, y) = K_j(|x - y|)$, then the field is called homogeneous (Jirsa 2009). Typical homogeneous kernels (Deco et al. 2008) consider excitation and inhibition and decay at infinity, e.g., in one spatial dimension $K(|x|) = a_e w(|x|) - a_i w(|x|) r$, and $w(x)$ is typically chosen as an exponential function or a Gaussian function. Figure 2 shows $K(|x|)$ for the most important connection kernel functions.

For instance, in one spatial dimension, the population firing rate arriving at spatial location x reads

$$P(x, t) = \int_{\Omega} K(|x - y|) S(\bar{U}(y, t)) dy$$

This mathematical implementation by an integral is not the only way to consider spatial interaction. Under certain conditions on the kernel function K , one finds the inverse of the spatial integral operator which is a partial differential operator (see, e.g., Jirsa (2009) and references therein)

Neural Field Model, Continuum, Fig. 2 Most important synaptic interaction kernel functions $K(|x|)$

$$D(\partial/\partial x)P(x, t) = S(\bar{U}(x, t))$$

Additional Physiological Elements

Putting elements (1–4) together leads to the standard neural field model with the properties that fit best to the real structure under study. To extend this standard model and render it more realistic, recent models add dynamic features:

Finite Axonal Transmission Speed

Action potentials propagate along axonal branches with a finite transmission speed leading to a delayed interaction between two spatial locations x and y . Assuming a single axonal transmission speed c , the population firing rate is (Coombes 2005; Jirsa 2009)

$$P(x, t) = \int_{\Omega} K(|x - y|) S\left(\bar{U}\left(y, t - \frac{|x - y|}{c}\right)\right) dy.$$

Heterogeneous Spatial Interaction

If the axonal connectivity depends on the spatial location and not just on the distance between two spatial locations, the neural field is not homogeneous. Previous studies have investigated the existence of both homogeneous and heterogeneous

axonal interactions $K(x, y) = K_{hom}(|x - y|) + K_{het}(x, y)$ yielding

$$P(x, t) = \int_{\Omega} K_{hom}(|x - y|) S(\bar{U}(y, t)) dy + Q(x, t)$$

with the additional nonlinear function

$$Q(x, t) = \int_{\Omega} K_{het}(x, y) S(\bar{U}(y, t)) dy$$

Spike Frequency Adaption

Metabolic processes modulate synaptic currents by a feedback mechanism dependent on the neural population activity, e.g., in visual perception (Bressloff 2012). In neural field models, considering these mechanism results into the so-called spike frequency adaptation which adds a current in the presence of high population activity (Coombes 2005; Bressloff 2012)

$$\begin{aligned} P(x, t) &= \int_{\Omega} K_{hom}(|x - y|) S(\bar{U}(y, t)) dy \\ &\quad - \int_{\Omega} f(|x - y|) a(y, t) dy \\ \hat{L}_a(d/dt)a(x, t) &= S(\bar{U}(x, t)) \end{aligned}$$

with the differential operator $\widehat{L}_a$, the recovery variable $a(x, t)$, and the spatial homogeneous interaction kernel of the feedback $a(x, t)$.

Synaptic Depression

It is well established that action potentials terminating at synapses may facilitate or depress synaptic action. In the case of synaptic depression in neural populations, the larger the population firing rate is, the smaller the synaptic gain $q(x, t)$ (Bressloff 2012):

$$P(x, t) = \int_{\Omega} K(|x - y|) q(y, t) S(\overline{U}(y, t)) dy,$$

$$\frac{\partial q(x, t)}{\partial t} = \frac{1 - q(x, t)}{\tau} - q(x, t) S(\overline{U}(x, t))$$

with the depression time constant τ .

Examples of Neural Field Models

The previous paragraphs have detailed the fundamental building blocks of neural field models involving various mathematical formulations, such as integral or differential description of synaptic responses or spatial axonal connectivity. By virtue of the diversity of these mathematical descriptions, in recent years research groups have derived and studied different neural field models. Historically, the first developed neural field equations are integral-differential equation of the types (Ermentrout 1998; Coombes 2005; Ermentrout and Terman 2010; Bressloff 2012)

$$\begin{aligned} \frac{\partial F(x, t)}{\partial t} = & -F(x, t) + S \left[\int_{\Omega} K(x - y) F(y, t) dy \right] \\ & + I(x, t), \end{aligned}$$

$$\begin{aligned} \frac{\partial V(x, t)}{\partial t} = & -V(x, t) + \int_{\Omega} K(x - y) S(V(y, t)) dy \\ & + I(x, t) \end{aligned}$$

with the external input variable $I(x, t)$. The first equation type describes the evolution of the population firing $F(x, t)$ and considers the spatial

interaction as argument of the transfer function (Wilson and Cowan 1973), whereas the second equation describes the evolution of the mean population voltage $V(x, t)$ implementing the transfer function under the spatial integral (Amari 1977). Both model types describe the evolution of different population activity variables but are equivalent and even may be transformed into each other. The combination of these equations allows to describe different neural structures (Bressloff 2012).

Certain spatial interaction kernels permit to inverse the spatial integral yielding a partial differential equation as described in the previous section. For instance, a typical model of this type describes the spatiotemporal evolution of the mean population potential by (Deco et al. 2008)

$$\begin{aligned} \left(\frac{1}{\gamma^2} \frac{\partial^2}{\partial t^2} + \frac{2}{\gamma} \frac{\partial}{\partial t} + 1 - r^2 \frac{\partial^2}{\partial x^2} \right) \phi(x, t) \\ = S(\overline{U}(x, t)) + I(x, t) \end{aligned}$$

$$\left(\frac{1}{\alpha\beta} \frac{\partial^2}{\partial t^2} + \left(\frac{1}{\alpha} + \frac{1}{\beta} \right) \frac{\partial}{\partial t} + 1 \right) \overline{U}(x, t) = g\phi(x, t)$$

in one spatial dimension. Here $\phi(x, t)$ is the pulse activity obeying a damped traveling wave equation with time scale $1/\gamma$ and spatial range r , and $I(x, t)$ is the external input. The pulses induce dendritic currents with time constants $1/\alpha$ and $1/\beta$ and synaptic gain g . As for the integral model, combinations of these coupled equations allow to derive a large family of different models adapted to real neural structures (Deco et al. 2008).

More recent studies have taken up the task to re-derive neural field equations considering the random nature of single neuron dynamics and networks. Such studies (see Sect. 6 in Bressloff 2012) reveal that the dynamics of the mean population activity depends strongly on the temporal or ensemble variance of the mean activity whose temporal evolution in turn depends on the mean activity. This strongly nonlinear interaction of mean and variance originates naturally from the presence of a large number of neurons (mean-field limit) and hence is supposed to reflect realistic neural behavior.

Spatiotemporal Dynamics

Neural field equations describe the spatiotemporal dynamics of neural populations. Both types of model equations shown in the previous section are nonlinear in the field variable: the integral model is nonlocal in space due to the general interaction kernel, whereas the partial differential equation model describes activity diffusion and is local in space.

Global Structures

Such structures emerge on the full domain. Figure 3 shows the emergence of spatiotemporal oscillations from a constant stationary state losing stability toward a spatially constant (Fig. 3a) and a spatially periodic (Fig. 3b) structure.

Another example of a global structure is propagating fronts which may emerge from the stimulation of a localized spatial patch. If the activated

region is too small (Fig. 4a), then the initial global activity structure is unstable and the system returns to the inactive state. If the initial center region is large enough (Fig. 4b), then the initial spatial structures broaden in size. The existence of the activation threshold (critical size of activated region) reflects the excitability of neural systems: too small perturbations from a stable stationary state relax to the stationary state, whereas perturbations large enough generate a strongly different activity pattern. This shows that the excitability known for single neurons translates to neural field on a population level (Hutt 2009).

Localized Structures

In addition to global structures, two stable stationary states may allow for localized structures, such as standing or propagating bumps, which are supposed to reflect the way how memory is stored in

Neural Field Model, Continuum, Fig. 3 Constant oscillations (left) and traveling waves (right) in a neural field

Neural Field Model, Continuum, Fig. 4 Generation of spreading activity representing two overlapping traveling fronts

Neural Field Model, Continuum,

Fig. 5 Unstable bump vanishes. (Taken from Fig. 7 in Coombes (2005) with permission)

the brain (Ermentrout 1998; Coombes 2005; Bressloff 2012). These structures may be stable or unstable subjected to physiological parameters. Figure 5 shows a localized unstable stationary standing bump over a stable constant stationary state. The bump is perturbed by small external fluctuations, starts to oscillate, and vanishes after some time. For large times, the constant stationary state remains the only state.

Neural Mass Action

Robert Kozma

Department of Mathematical Sciences, University of Memphis, Memphis, TN, USA

Synonyms

[K-set hierarchy](#)

Definition

Neural mass action is a field of synchronized axonal pulse firings that cortical neurons create and impose on themselves and others by distributed synaptic interactions. Neural mass action combines sensory representations with memories and binds them into percepts.

Basic Features of Mass Action in Neural Populations

Freeman described mass action (FMA) in the nervous system based on electrocorticogram (ECoG) measurements with electrodes implanted on the cortical surface of animals and in human subjects with their consent during epilepsy surgery (Freeman 1975; Barrie et al. 1996; Freeman et al. 2003; Freeman and Kozma 2010). FMA self-organizes the spontaneous cortical background activity at criticality by continuous mutual excitation (positive feedback) among pyramidal cells at intensities related to the degree of arousal. FMA activity is segmented into wave packets by beats in narrowband oscillations that are sustained by inhibition from interneurons (negative feedback). FMA converts a sensory representation of a stimulus, which is expressed in microscopic trains of pulses, into a percept of the stimulus, which is expressed in a mesoscopic spatial pattern of amplitude modulation (AM) of a narrowband carrier wave.

FMA is measured indirectly by recording potential fields, which are formed by the flow of dendritic current across the resistance of brain and scalp tissues. The sequence of metastable AM patterns can be viewed as frames in a movie, separated by the collapse of AM patterns (null spike), analogous to the shutter (Freeman and Kozma 2010; Kozma and Freeman 2009). Extraction of the forms of FMA that define the wave packet and modeling the neural mechanism of perception require both broad fields of view and high resolution in the spectral, temporal, and spatial domains of measurement, straining the limits of contemporary neuroscience technology and theory (Freeman et al. 2003; Ruiz et al. 2010).

Examples of AM patterns in the theta band are displayed in Fig. 1, as they evolve in time between time instance 3.56 and 3.72 s. In these experiments, the electrical activity of the primary visual cortex in rabbits was measured using an 8×8 array of chronically implanted electrodes (Barrie et al. 1996). The space between the electrodes is 0.79 mm covering an area of 5.6×5.6 mm. Data were collected during 6 s using a 500 Hz sampling frequency. In Fig. 1, dark and light tones indicate low and high amplitudes,

Neural Mass Action, Fig. 1 Temporal evolution of spatial amplitude-modulation (*AM*) patterns. There is an apparent rotation in the vortex counterclockwise from $t = 3.56$ – 3.72 s. (After Rodriguez and Kozma 2007)

respectively. One can observe practically a complete rotation during the given sequence of amplitude frames of duration 0.26 s. These results show that the synchrony is not completely lost during the transitional period at the null spike; rather it is represented by sequentially appearing semi-localized mesoscopic vortex structures.

Hierarchical Neural Population Models to Describe Neural Mass Action

The cortical fields created by FMA are much larger than the synapses and neurons supporting them, and the frequency components are much slower than those of action potentials, so mesoscopic measurements can be modeled as continuous variables. The pulse frequencies of incoming trains of pulses determine the dendritic current amplitude. The current amplitude controls the output pulse frequencies. The wave amplitude

summed from a local neighborhood (a wave density) is correlated in time and space with the pulse density of neurons in the same neighborhood. The statistical relation of pulse density on axons to wave density on dendrites is characterized by an asymmetric sigmoid function, which is used as a basic component of Freeman K models (Freeman and Erwin 2008). A hierarchical approach to neural dynamics from microscopic to mesoscopic and macroscopic populations is summarized as the ten building blocks of neurodynamics (Freeman 1975; Skarda and Freeman 1987; Freeman 2001):

1. State transitions of an excitatory population from a point attractor with zero activity to a nonzero point attractor with steady-state activity by positive feedback
2. Emergence of oscillations through negative feedback between excitatory and inhibitory neural populations

3. State transitions from a point attractor to a limit cycle attractor that regulates steady-state oscillation of a mixed excitatory-inhibitory cortical population
4. Genesis of chaos as background activity by combined negative and positive feedback among three or more mixed excitatory-inhibitory populations
5. Distributed wave of chaotic activity that carries a spatial pattern of amplitude modulation made by the local heights of the wave
6. The increase of nonlinear feedback gain that is driven by input to mixed population, which results in construction of an amplitude-modulation pattern as the first step in perception
7. The embodiment of meaning in amplitude-modulation patterns of neural activity, which are shaped by synaptic interactions that have been modified through learning
8. Attenuation of microscopic sensory-driven noise and enhancement of macroscopic amplitude-modulation patterns by divergent-convergent cortical projections
9. Gestalt formation and pre-afference through the convergence of external and internal sensory signals leading to the activation of the attractor landscapes and leading to intentional action
10. The formation of a sequence of global amplitude-modulation patterns of chaotic activity that integrates and directs the intentional state of an entire hemisphere

Various components of these principles have been implemented in computational models. For example, the Freeman Katchalsky K models use a set of ordinary differential equations (ODEs) with distributed parameters to describe the hierarchy of neural populations starting from micro-columns to the hemispheres (Kozma and Freeman 2001, 2009). Recent advances include neuropercolation implementations of K sets using random graph theory (Kozma 2008; Kozma and Puljic 2013).

Definition

Neuronal population models refer to a class of models that describe the temporal evolution of one or more statistical moments that characterize the dynamical state of interconnected populations of neurons. Existing neuronal population models, for mathematical tractability and direct connection with experiment, are generally restricted to the temporal evolution of mean quantities such as the mean firing rate or mean (soma) membrane potential over an appropriately defined neural ensemble. Such an ensemble is typically defined in terms of the physical domain over which the activity of functionally identical neurons can be, statistically speaking, assumed spatially homogeneous.

Detailed Description

History

By postulating that, in analogy to the collective phenomena of atomic interaction underpinning ferromagnetism, neurons acted cooperatively, Cragg and Temperley (1954) provided the first clear rationale for modeling the collective

behavior of populations of neurons. They argued that dense functional interactions between neurons would lead to the emergence of large-scale (compared to the dimensions of the individual neuron) domains of coordinated activity having features that could not be understood by appealing to the behavior of the single neuron. While often regarded as the basis for Ising-based models of networks of enumerable neurons (see entry ► [“Hopfield Network”](#)), it also stimulated efforts to understand the collective properties of neurons based on more specific and relevant anatomical and physiological predicates.

Early Mathematical Developments

While McCulloch and Pitts (1943), Ashby (1950) and Rapoport (1950), among others, had made a variety of abstract attempts to mathematically formalize the interactions between populations of neuron-like elements and to characterize their collective properties, it was Beurle (1956) who is generally acknowledged for developing the first dynamical description of a mass of neurons. In this theory, the dynamics of continuously distributed populations of excitatory neurons, having a fixed firing threshold, were studied. This formulation was central to the subsequent development of neuronal population models because of the explicit mathematical definitions of population neuronal activity, bulk (population) synaptic feedback and synaptic delay, and mean integrated excitation.

The first attempt to account for a physiologically measurable phenomena (prepyriform EEG) in terms of the modeled properties of populations of neurons may be attributed to Freeman (1964). This model aimed to account for the oscillatory prepyriform average evoked potential in terms of a distributed population of cortical pyramidal (excitatory) neurons, receiving an impulse-driving input and interacting with each other via recurrent inhibition. Pyramidal neurons received input from the lateral olfactory tract which was then dispersed in time due to the distributed delay effected by the cable properties of the pyramidal cell dendrites and convolved with a simple exponential function corresponding to the unitary excitatory postsynaptic potential (EPSP). The

resulting postsynaptic activity was then linearly transduced into efferent pulse activity to excite a feedback interneuron population, the activity again dispersed in time due to an undefined combination of conduction, synaptic, and electrotonic delays. Mathematically this sequence of neuronal population events was formulated as a linear transfer function containing transcendental terms corresponding to the various distributed delays. This *cortical transfer function* (see entry ► [“Transfer Function, Electro cortical”](#)), subsequently approximated by a rational function for empirical comparison and parameter evaluation, introduced a number of concepts central to the development of almost all future population neural models – feedback between functionally distinct neuronal populations, the dynamics of population averaged postsynaptic potentials, the transduction of averaged integrated postsynaptic activity to a continuously defined average pulse (spike) rate (subsequently referred to as “wave-to-pulse” conversion), and the transformation of incoming population pulse (spike) trains to postsynaptic potentials (later to be designated “pulse-to-wave” conversion). This lumped negative feedback model of cortical dynamics was later further elaborated to include positive feedback loops for mutual excitation and inhibition in the respective inhibitory and excitatory neuronal populations and to include an amplitude-dependent, and hence nonlinear, neuronal population feedback gain – the precursor of the static sigmoid nonlinearity (Freeman 1967). This lumped configuration of neuronal populations not only encapsulated the topology of synaptic interactions in mature neuropil but also introduced the main features of the K-set hierarchy of neural population interactedness (see below) – a schema that was to exert a prominent influence in the development of later neuronal population models.

Commencing in the early 1970s, a number of approaches were developed to modeling populations of neurons that were to introduce a range of conceptual innovations that would have a commanding influence on all ensuing approaches. Particularly notable were the works of Wilson and Cowan (1972) and Lopes da Silva et al. (1974).

Wilson and Cowan derived a pair of coupled nonlinear ordinary differential equations describing the short-time averaged dynamics of the spatial mean ring rates of interacting excitatory and inhibitory neuronal populations. Of crucial significance was their introduction of the *sigmoidal firing rate function* and an explicit cortical mesocircuit quantitatively defined by population (synaptic) connectivity coefficients. Because mean ring rates characterized neuronal population dynamics, this, and similarly formulated models, was developed in terms of the *activity* of a neuronal population. Arguably Grossberg (1967) had mathematically anticipated this formulation by deriving an “additive STM (short-term memory) equation”; however, the inspiration for such a formulation was principally psychological (Hebbian) and as such its domain of application was that of enumerable networks of neurons rather than populations or masses.

In contrast to, but inspired by, this model, Lopes da Silva et al. (1974) subsequently presented a population model of the ventro-posterolateral thalamus, in which they dynamically characterized the *average membrane potential* of reciprocally connected populations of excitatory thalamocortical relay cells and inhibitory interneurons. Novel to this approach was the formal inclusion of average unitary excitatory and inhibitory postsynaptic potentials (PSPs) described by weighted bi-exponentials.

Physiological and Anatomical Representations

Two essential premises distinguish neural population models from biological recurrent neural networks: firstly, that individual neurons in a circumscribed area (e.g., a cortical macrocolumn; see entry ► [“Mesoscopic Anatomy and Neural Population Models”](#)) need not be enumerated and secondly, that in this circumscribed area, the connectivity between neurons is random and non-specific to the extent that the inner circuitry cannot, or need not, be meaningfully specified. The consequence of this is that for each bounded neural population, the spatial and temporal microstructure, or microstates, of neural activity can be disregarded in favor of characterizing the

population's dynamical state in terms of certain average (or higher order) properties or macrostates. In this way the dense and complex interactions between individual neurons can be replaced by effective averages – the mean fields – between populations of neurons.

In general the contention of a population macrostate is expected to remain valid as long as interneuronal propagation delays are negligible compared to local synaptic and dendritic cable delays (see below), and there is no characteristic spatial structure to population neuronal connectivity. However, in modeling spatially extended neural populations, such as the neocortical sheet, neuronal connectivity typically exhibits a substantial degree of spatial organization (see entry ► [“Mesoscopic Anatomy and Neural Population Models”](#)) with the corresponding propagation delays no longer negligible. Thus, spatially extended formulations of neural population models have to be implemented by either constructing networks of neural populations (see entry ► [“Neuroimaging, Neural Population Models for”](#)) or by assuming that the neural populations, continuously distributed in space, interact via spatially dependent connectivity functions (see entry ► [“Neural Field Model, Continuum”](#)).

Most neural population models can be understood in terms of a sequence of serial physiological transformations between synaptic input and axonal output in terms of a mean neuron. The mathematical definition of a mean neuron is easily motivated by spatially averaging (or coarse-graining) a discrete set of functionally homogeneous neurons over a physical domain corresponding to the length scales of the random/nonspecific interneuronal connections and by assuming that membrane potential fluctuations due to spiking are uncorrelated. The serial physiological transformations generally include synaptic delays, transduction of postsynaptic potentials, neuronal cable delays/passive electrotonic processes, and action potential generation.

Neuronal Populations, Hierarchies, and Connectivity

A typical starting point for the formulation of neuronal population models requires the

specification of functionally homogeneous neural populations and the topology of their interactions, driven by histological considerations of the cellular composition and anatomical organization of neural tissue. Because all neurological processes of any complexity depend on the interaction of excitatory and inhibitory neurons, anatomically circumscribed populations of these respective populations form the basis of, with certain weak exceptions (see, e.g., Amari 1975, 1977), all neuronal population models. Figure 1 schematically represents the circuit topologies for all the major neuronal population models (see also entry ► [“Neural Field Model, Continuum”](#)).

Based on the histological properties of the mammalian olfactory bulb and prepyriform cortex, Freeman (1975) defined a hierarchical scheme of interaction in which populations of excitatory and inhibitory neurons interact over progressively larger physical scales. The schema, referred to as the K-set hierarchy (in honor of the biophysical chemist Aharon Katchalsky), commences with the simplest type of neural population referred to as the *KO* set (or noninteractive K set). This set, or neural population, is defined as a population of 10^3 – 10^8 neurons having a common source of input, a common sign of output, and no functional interaction. The K-set hierarchy is then next extended to the case where there exist dense, but random and nonspecific, interactions between neurons of any given *KO* set. This defines the so-called *KI* set or interactive *KO* set, of which there are two types: the *KI_e* set, consisting of mutually excitatory neurons, and the *KI_i* set, comprised of mutually inhibitory neurons. Dense functional interactions between two *KI* sets, *KI_j* and *KI_k*, define the interactive *KII* set such that $KII_{jk} \equiv KII_{kj}$. The K-set hierarchy can then be extended in a straightforward manner to *KIII* and *KIV* sets. While the exact topology of these sets ultimately depends on certain peculiarities of Freeman's mass action approach, it is nevertheless capable of serving as a general schema for characterizing neuronal population architectures. For example, in terms of neocortex, *KI_e* can be identified with populations of pyramidal neurons densely interacting via recurrent axonal collaterals (see entry ► [“Mesoscopic Anatomy and Neural Population Models”](#)) and

Neural Population

Model, Fig. 1 Schematic representation of the principle neural population model circuit topologies segregated by the form of the postsynaptic response. All approaches consider functionally differentiated excitatory (E) and inhibitory (I) neuronal populations. *Open circles* represent excitatory connections, *filled circles* inhibitory ones, and *half-filled circles* both. (Figure adapted from Liley et al. 2012)

KI_i could correspond to one or more local inhibitory interneuron populations, KII_{ie} the resulting macrocolumn and $KIII$ and KIV , respectively, the cortical area and region/lobe. However, care has to be taken in defining neural sets. For example, the fact that the apical dendrite of a single pyramidal (excitatory) neuron can extend across multiple neocortical layers means that cortical lamination represents an insufficient anatomical basis on which to define a KO neural population.

While it is often assumed that the functional interactions between neurons are exclusively axosynaptic, there is no requirement that this restriction need be observed in the construction

of neural population models or in order to justify their physiological utility. It is now known that the functional structure of mammalian cortical tissue extends well beyond neurons and their axosynaptic interactions. For example, neurogliaform cells, rather than solely providing structural and biochemical support for the neuronal parenchyma as previously thought, have been shown to regulate neuronal activity through a complex involving astrocytes and neuronal pre- and postsynaptic terminals (see entry ► [“Tripartite Synapse \(Neuron–Astrocyte Interactions\), Conductance Models”](#); Giaume et al. 2010). Further other forms of neuronal interaction have

either been suggested (ephaptic or local field; Terzuolo and Bullock 1956) or demonstrated (gap junction/dendrodendritic, axo-myelinic, axo-axonic, volume/extrasynaptic; Sohl et al. 2005; Stys 2011; De-Miguel and Fuxe 2012; Mozzachiodi and Byrne 2010). The addition of such biological complexity, rather than undermining a neural population modeling approach, arguably serves to further justify abandoning the idea of articulating neuronal microstates in favor of a population macrostate.

Neuronal Structure and Dendritic Filtering

Neural population models generally take a parsimonious approach to describing the electrical properties of populations of neurons. The most basic approach is to simply assume that the average neuron behaves as a summing junction for induced postsynaptic potentials

$$V_i = \sum_j \text{PSP}_{ij}(t), \quad (1)$$

where V is the mean neuronal membrane potential or mean soma membrane potential (to emphasize the membrane potential locus that regulates neuronal firing) and $\text{PSP}_{ij}(t)$ represents the magnitude of the average induced postsynaptic potentials of type j at time t on neurons of type i .

A better approach is to consider the extended electrotonic neuron collapsed down to a point parallel-resistive circuit, representing the neuronal membrane, into which all synaptically induced activity terminates. In this case the temporal evolution of $V(t)$ is simply described by a *current-based neuron*

$$\tau dV_i/dt = -V + \sum_j \text{PSP}_{ij}(t), \quad (2)$$

where τ defines a mean membrane time constant. However, because the magnitude of any induced postsynaptic activity depends upon the state of the postsynaptic membrane, given that presynaptically released neurotransmitters regulate postsynaptic ionic conductances, the evolution of $V(t)$ may be described in terms of the alteration of a

mean equivalent conductance. On this basis a *mean conductance-based neuron* is defined as

$$\tau dV_i/dt = -V + \sum_j \psi_j(V_i) \text{PSP}_{ij}(t), \quad (3)$$

where $\psi_j(V_i)$ represents a dimensionless ionic driving force.

Synaptic Activity

From a physiological perspective, the time course of the postsynaptic potential felt at the neuronal soma represents a combination of the kinetics of neurotransmitter action and neuronal cable delays. In the simplest case, these effects can be ignored such that the unitary population postsynaptic potential (or population postsynaptic impulse response) $\alpha_{ij}(t)$ is

$$\alpha_{ij}(t) = A_{ij} \delta(t), \quad (4)$$

where A_{ij} is the peak amplitude (positive for excitatory postsynaptic potentials, negative for inhibitory postsynaptic potentials) and $\delta(t)$ the Dirac delta function corresponding to the arrival of a single presynaptic action potential. However, given the extended nature of the neuronal dendritic tree and the temporal variations in postsynaptic potentials of various types, such delays can generally not be ignored. On this basis, following Rall (1967), the unitary postsynaptic impulse response, $\alpha_{ij}(t)$, is better described by a function that rises to a peak and then decays away:

$$\alpha_{ij}(t) = A_{ij} a_{ij} t \exp [1 - a_{ij} t] \Theta(t), \quad (5)$$

where $\alpha_{ij}(t = 1/a_{ij}) = A_{ij}$ is the peak amplitude and $\Theta(t)$ the Heaviside step function. While it is often assumed that $a_{ij} \equiv a_i$ depends only on the postsynaptic population, there is mounting physiological evidence to suggest that the configuration of postsynaptic ionic channels depends upon certain properties of the presynaptic neurons. Other normalizations of this function, for example, to fixed area, are also possible. Because $F_j(t') dt'$ action potentials arriving at t' about t would be expected to contribute $d\text{PSP}_{ij}(t) = \alpha_{ij}(t-t') F_j(t') dt'$ to the population postsynaptic potential we find, assuming additivity of response,

$$\text{PSP}_{ij}(t) = \int_{-\infty}^t \alpha_{ij}(t-t') F_j(t') dt'. \quad (6)$$

In neural population models, it is found convenient to reformulate this convolution in terms of a critically damped oscillator driven by $F(t)$:

$$(d/dt + a_{ij})^2 \text{PSP}_{ij}(t) = A_{ij} a_{ij} \exp(1) \cdot F_j(t). \quad (7)$$

The form of this, and similar differential equations, is easily established by finding a linear differential operator L such that $L\alpha(t) = \delta(t)$. As is similarly done in Green's function formulations of integral continuum neural field equations (see entry ► “[Neural Field Model, Continuum](#)”) to obtain partial differential equation representations, such differential equations are most simply found by taking either the Fourier or Laplace transforms of α_{ij} with respect to t and identifying $s = i\omega \leftarrow d/dt$. It is often found desirable to have more flexibility in specifying the shape of the population postsynaptic response, and therefore, bi-exponential generalizations of the alpha function can be utilized (Fig. 2). Two such formulations that have been found particularly useful are

$$\begin{aligned} [d/dt + a(\epsilon)][d/dt + \tilde{a}(\epsilon)] \text{PSP}(t) \\ = A\tilde{a}(\epsilon) e^{a(\epsilon)/a_0} \cdot F(t), \end{aligned} \quad (8)$$

$$\begin{aligned} a(\epsilon) &= \epsilon a_0 / (e^\epsilon - 1), \tilde{a} = a(\epsilon) e^\epsilon; \\ \epsilon &\geq 0, \end{aligned} \quad (9)$$

and

$$\begin{aligned} (d/dt + a)(d/dt + b) \text{PSP}(t) \\ = A(b - a)/k \cdot F(t), \end{aligned} \quad (10)$$

$$k = (a/b)^{a/(b-a)} - (a/b)^{b/(b-a)}; a < b, \quad (11)$$

where the subscripts specifying the type of postsynaptic potential have been dropped for clarity. The first of these is useful if the independent parametric regulation of rise and decay times is necessary, as, for example, in modeling the effects of anesthetics on postsynaptic kinetics (see below). The effects of bulk synaptic plasticity can be modeled by assuming that a_{ij} and A_{ij} are activity-dependent functions of population activities F_i and F_j .

Pulse Generation

The closure of equations defining neural population models depends on formally specifying the

N

Neural Population Model, Fig. 2 Illustration of the forms of postsynaptic potentials utilized in neural population models and their corresponding differential structure. The modeled postsynaptic potential on the left corresponds

to the well-known alpha function introduced by Rall (1967). The modeled postsynaptic potentials on the right illustrate a parametric form that allows the independent specification of the rise and fall phases

relationship between mean (soma) neuronal population membrane potential and the generation of axonal spikes. While the generation of the post-synaptic response depends on innovating axonal spikes, because of the assumption of dense and random intrapopulation connectivity, the timing of individual spikes is not defined. For this reason, neural population models define axonal activity in terms of the total number of spikes $F_j(t)dt$ generated in the interval $[t, t + dt]$ via a time-dependent firing rate function $F_j(t)$. The simplest approach to the construction of such a firing rate function is to assume that it is an instantaneous bounded monotonic function (logistic) of the mean population (soma) membrane potential,

$$F_j(t) \equiv F_j(V_j[t]) = F_j^{\max} / \{1 + \exp[-c_j(V_j - \theta_j)]\}, \quad (12)$$

i.e., a sigmoid or squash function having maximal slope $c_j F_j^{\max}/4$ at $V_j = \theta_j$. θ_j nominally defines a neuronal population threshold. This and similar sigmoids (e.g., error function, arctangent, etc.) are often described as being symmetric because $dF/dV|_V = dF/dV|_{2\theta - V}$. Asymmetric sigmoid functions can also be defined, for example,

$$F_j(V_j) = F_j^{\max} - F_j^{\max} \{1 + \exp[-c_j(V_j - \theta_j)]\}^{-k}; \quad c_j, k > 0, \quad (13)$$

$$F_j(V_j) = F_j^{\max} \{1 - \exp[-c_j \exp(V_j - \theta_j)]\}; \quad c_j > 0, \quad (14)$$

the latter of which has been used in modeling the neuronal population dynamics of mammalian olfactory bulb (Freeman 1979). Firing rate functions can also be motivated by considering the unimodal distribution of firing thresholds in a population of neurons having a fixed absolute refractory period. For example, following Beurle (1956), Wilson and Cowan (1972, 1973) described neural population activity $F_j(t)$ in

terms of the fraction of neurons that receive at least a threshold level of excitation per unit time that are able to fire (i.e., not refractory) on the assumption that there is no correlation between the suprathreshold and refractory fractions, i.e.,

$$F_j(t + \tau)dt = R_j(t) \cdot S_j(V_j)dt, \quad (15)$$

$$= \left\{ 1 - \int_{t-r_{\text{abs}}}^t F_j(t')dt' \right\} \cdot \int_{-\infty}^{V_j} f_V(v)dvdt, \quad (16)$$

where $R_j(t)$ is the fraction of neurons of type j that are able to fire at time t , $S_j(V_j)$ the fraction of neurons per unit time that receive at least a threshold level of activation V_j , r_{abs} the spike refractory period, $f_V(\cdot)$ a unimodal neuronal firing threshold distribution function, and τ a nominal synaptic operating delay. By assuming that τ and r_{abs} are small compared to the time scale of variations in $F_j(t)$, it can be easily shown that $0 \leq F_j(t) < 1/(1 + r_{\text{abs}}) \equiv F_j^{\max}$.

Canonical Formulations

Among the most important and influential neural population models is that developed by Wilson and Cowan (1972, 1973). Based on the topological structure of mature neuropil suggested by Freeman (1967), they developed a set of planar nonlinear differential equations describing the activity of coupled, spatially lumped, populations of excitatory and inhibitory neurons. As originally formulated, they made use of the concept of temporal coarse-graining, first applied to problems in statistical physics, to derive equations of motion for the respective time averaged neuronal population firing rates. For pedagogical purposes, these equations can be easily, though not rigorously, derived. By assuming postsynaptic potentials are described by Dirac delta functions (Eq. 4) and linearly sum (Eq. 1), we find from Eq. 15 that

$$F_E(t + \tau) = \left\{ 1 - \int_{t-r_E}^t F_E(t')dt' \right\} \cdot S_E[A_{EE}F_E(t) + A_{EI}F_I(t)], \quad (17)$$

$$F_I(t + \tau) = \left\{ 1 - \int_{t-r_I}^t F_I(t') dt' \right\} \cdot S_I[A_{IE}F_E(t) + A_{II}F_I(t)], \quad (18)$$

with $E, I = \text{excitatory, inhibitory}$.

By reinterpreting $\tau_{E,I} \ll r_{E,I} (\equiv r_{\text{abs}})$ as the combined characteristic time scale for uniform synaptic, cable, and axonal delays, we obtain, after first-order expansion in t and the addition of external inputs $Q(t)$ and $P(t)$,

$$\tau_E \frac{dF_E(t)}{dt} = -F_E(t) + \{1 - r_E F_E(t)\} \cdot S_E[A_{EE}F_E(t) + A_{EI}F_I(t) + P(t)], \quad (19)$$

$$\tau_I \frac{dF_I(t)}{dt} = -F_I(t) + \{1 - r_I F_I(t)\} \cdot S_I[A_{IE}F_E(t) + A_{II}F_I(t) + Q(t)], \quad (20)$$

This coupled pair of nonlinear ordinary differential equations represents the well-known spatially lumped Wilson and Cowan equations. The equations, and subsequent extensions and modifications, are widely used in the modeling of coupled neuronal population activity. These equations represent an example of an *activity-based* neuronal population model (see below). Extensions to continuously distributed populations of interacting excitatory and inhibitory neurons in planar sheets are easily formulated (see entries ► “[Neural Field Model, Continuum](#)” and ► “[Wilson-Cowan Model](#)”).

An alternative approach to formulating a neuronal population model is to develop equations of motion in terms of the mean (soma) membrane potential of the respective neural masses. A particular advantage to this approach is that the mean soma membrane potential can be more naturally linked to meso- and macroscopic physiological measurements such as the local field potential (LFP), the EEG, and the electrocorticogram (ECoG). An important basis for this approach was the lumped neuronal population

model developed by Lopes da Silva et al. (1974) to explain the rhythmic origins of the mammalian alpha rhythm. In this model, a “feedforward” population of excitatory neurons receives external excitatory input and inhibitory feedback from inhibitory interneurons. Originally formulated as a model of thalamic tissue, a modified form is now widely used to model cortical neuronal population dynamics (see entry ► “[Jansen-Rit Model](#)”). The equations describing the model of Lopes da Silva et al. (1974), which can be seen to follow in a fairly straightforward manner from Eqs. 1 and 10, are

$$\begin{aligned} & \left(\frac{d}{dt} + a_E^1 \right) \left(\frac{d}{dt} + a_E^2 \right) V_I(t) \\ &= A_E (a_E^2 - a_E^1) \cdot C_{IE} F_E \underbrace{[\text{PSP}_{EP}(t) - \text{PSP}_{EI}(t)]}_{\equiv V_E(t)}, \end{aligned} \quad (21)$$

$$\begin{aligned} & \left(\frac{d}{dt} + a_I^1 \right) \left(\frac{d}{dt} + a_I^2 \right) \text{PSP}_{EI}(t) \\ &= A_I (a_I^2 - a_I^1) \cdot C_{EI} F_I [V_I(t)], \end{aligned} \quad (22)$$

$$\begin{aligned} & \left(\frac{d}{dt} + a_E^1 \right) \left(\frac{d}{dt} + a_E^2 \right) \text{PSP}_{EP}(t) \\ &= A_E (a_E^2 - a_E^1) \cdot P(t), \end{aligned} \quad (23)$$

where $P(t)$ is an external excitatory pulse input and $C_{IE,EI}$ are defined as the average number of axosynaptic contacts that an excitatory neuron makes on an inhibitory interneuron and an inhibitory interneuron makes on an excitatory neuron, respectively. All other symbols have been defined previously. These equations are an exemplar of a *voltage-based* neuronal population model (see below).

Contemporary neural population models, in order to best approximate known physiology, utilize features of both of these canonical modeling approaches (Deco et al. 2008). An example of such a model is the spatially lumped approximation that can be obtained from Liley et al. (2002) by ignoring long-range axonal connectivity. The resulting model equations, developed on the basis of the *mean conductance-based* neuron, can be written as

$$\tau_i \frac{dV_i(t)}{dt} = -V_i(t) + \sum_j \frac{V_{ij}^R - V_i(t)}{|V_{ij}^R|} \text{PSP}_{ij}(t), \quad (24)$$

$$\left(\frac{d}{dt} + a_{ij} \right)^2 \text{PSP}_{ij}(t) = a_{ij} A_{ij} \exp(1) \{F_j[V_j(t)] + P_{ij}(t)\}, \quad (25)$$

where a normalized ionic driving force has been explicitly defined in terms of the synaptic reversal potential V_{ij}^R and $P_{ij}(t)$ represents an external pulse input. Such a formulation is typically restricted to single distinct excitatory and inhibitory neural populations.

Voltage Versus Activity-Based Models

A number of authors (Bressloff 2012; Ermentrout 1998) have made a distinction between neuronal population models in terms of whether they are *activity based* or *voltage based*. To see this distinction, consider the following generalized representation of a population model involving multiple coupled populations:

$$L_i V_i = \sum_j \text{PSP}_{ij}(t), \quad (26)$$

$$\hat{L}_{ij} \text{PSP}_{ij}(t) = k_{ij} F_j[V_j(t)], \quad (27)$$

where L_i and $\hat{L}_{ij}$ represent linear differential operators. If the derivatives in L_i vanish (i.e., the time scales of postsynaptic potentials dominate), then we have

$$\hat{L}_{ij} \text{PSP}_{ij}(t) = F_j \left[\sum_i k_{ji} \text{PSP}_{ji}(t) \right], \quad (28)$$

where we have redefined $\text{PSP}_{ij} \rightarrow k_{ij} \text{PSP}_{ij}$. This is said to define an *activity-based* model.

If instead the derivatives in $\hat{L}_{ij}$ vanish (i.e., the time scales of passive electrotonic properties dominate), then we have

$$L_i V_i = \sum_j k_{ij} F_j[V_j(t)], \quad (29)$$

then we have a *voltage-based* model. In practice, however, the distinction between activity- and voltage-based models is not that important as physiologically the time scales of synaptic kinetics and passive neuron properties are of the same order of magnitude such that neither of these limits will be applicable.

Solutions of Deterministic Neuronal Population Equations

The properties of neural population models can be established using all the standard mathematical and computational methods that are typically used to investigate the dynamics of coupled non-linear systems such as phase-plane analysis and numerical bifurcation methods. However, it is also useful to explicitly consider linearizations of the defining equations, as it assists in determining whether the structure of the population model accords with the physiological measurements of the system being modeled. This is particularly the case in attempts to account for rhythmic EEG activity in terms of the activity of recurrently connected populations of cortical and thalamic neurons. For example, Lopes da Silva et al. (1974), by assuming a stable steady state (V_E^*, V_I^*) about which a linearization could be performed, were able to rewrite their model's defining equations in transfer function form as

$$V_E(f) = \frac{A_E(a_E^2 - a_E^1)(2\pi if + a_I^1)(2\pi if + a_I^2)}{(2\pi if + a_E^1)(2\pi if + a_E^2)(2\pi if + a_I^1)(2\pi if + a_I^2) + K} P(f), \quad (30)$$

$$K = C_E C_I A_E A_I (a_E^2 - a_E^1)(a_I^2 - a_I^1) dF_E/dV_E|_{V_E^*} dF_I/dV_I|_{V_I^*} \quad (31)$$

where f is frequency and G_E , particularly in the context of neural population models of the EEG, is typically referred to as the *electrocortical transfer function* (see entry ► “[Transfer Function, Electrocortical](#)”) and enables the determination of a theoretical power spectrum $|V_E(f)|^2 = |G_E(f)|^2 |P(f)|^2$. If it is further assumed that $|P(f)|^2$ is flat (i.e., mean external ring rates can be described by a Gaussian white noise process) then the poles of $G_E(f)$ will determine the dominant spectral components (or resonances) of the power spectrum. This approach is exploited by a number of neural population models of the EEG (Liley et al. 2002, 2003; Robinson et al. 2002; Steyn-Ross et al. 1999) in order to facilitate comparison with experimental recordings.

While the dynamics of planar formulations of neural population models are restricted to hysteresis and limit-cycle activity, higher order population models are capable of exhibiting substantial dynamical complexity, such as multistability, bursting, and chaos, as well as complex, and potentially novel, bifurcation scenarios due to the large number of irreducible model parameters. For example, the spatially homogeneous Liley equations (Liley et al. 2002) (see entry ► “[Down Under Neural Population Models](#)”) can spawn chaos (see entry ► “[Chaos, Neural Population Models and](#)”) through a co-dimension of one homoclinic Shil’nikov saddle-node bifurcation (not to be conflated with a saddle node on an invariant circle bifurcation) (van Veen and Liley 2006).

Stochastic Models

At the level of the single neuron, there are many sources of noise – noise generated by thermally induced fluctuations in the state of ion channels and the noise generated due to the probabilistic vesicular release of neurotransmitter being among the most important (Longtin 2013). The effects of such noise are assumed to contribute to the stochastic variability of neuronal activity, such as the near Poisson pulse trains that are characteristic of many cortical neurons (Softky and Koch 1993). However, it is neither straightforward nor obvious how noise at the single neuron level translates into noise and fluctuations in activity at the neuronal

population level and therefore how the addition of this noise qualitatively shapes the dynamical activity of the neural mass. For this reason, a variety of theoretical attempts have been developed in an attempt to address this issue systematically. One important approach has been to conceive the dynamics of populations of spiking neurons in terms of the temporal evolution of the probability density of the soma membrane potentials. The resulting formulations, typically referred to as *population density methods* (see entry ► “[Population Density Model](#)”), typically assume a highly simplified model of a neuron (generally the leaky-integrate-and-fire) and either fully or sparsely connected neuronal networks. Nevertheless no rigorous approach has yet emerged to derive neural population models that take proper account of noise-induced fluctuations or the statistical correlations between neurons. Further complicating such attempts is the absence of any clear framework for how to deal with the reported effects that non-neuronal components may have. For this reason, stochastic extensions to deterministic neural population models are largely phenomenologically motivated. The general phenomenological approach can be illustrated by considering the indefinite voltage-based population model evolving according to a Langevin (stochastic differential) equation of the form

$$\tau_i dV_i(t) = \left\{ -V_i(t) + \sum_j k_{ij} F_j[V_j(t)] \right\} dt + dW_i(t), \quad (32)$$

where $dW_i(t)$ is a Wiener process. In the case that the modeled source of noise arises from fluctuations about an asynchronous state due to finite (network) size effects, then the population Wiener noise processes will be spatially correlated, i.e., $\langle dW_i(t) dW_j(t) \rangle = \nu > 0$ for all i, j . In the case that the source of noise is due to membrane potential fluctuations, then $F_j[V_j(t)]$ will be redefined as the expectation $\mathbb{E}(F_j[V_j(t)])$ such that a fully implicit set of stochastic differential equations result (Bressloff 2012).

Applications and Relationship to Physiological Measurement

Despite their sometimes phenomenological construction, the importance of neuronal population models lies in their ability to serve as a framework for understanding the physiological genesis of a range of macroscopic scale neurophysiological phenomena, such as spontaneous and evoked EEG, and the relationships of such activity to other bulk measures of brain function such as BOLD (blood oxygen level-dependent) MRI. For this reason, neural population models are often characterized as “mesoscopic bridges” – in that phenomenological descriptions of molecular/cellular level activity can be linked with large-scale activity through an intermediate (mesoscopic) bridging theory (Foster et al. 2008). Examples of phenomena that are particularly amenable to a neural population model description are the mammalian alpha rhythm and the various sensory (visual, auditory, somatosensory)-evoked potentials.

Spontaneous and Evoked EEG

Scalp-recordable electrical activity exhibits a number of dynamical phenomena that can be and have been characterized by neural population models. Among the most important of these is the mammalian alpha rhythm. The 8–13 Hz alpha rhythm is arguably the most ubiquitous rhythmic phenomena seen in scalp EEG. First discovered by Hans Berger in the late 1920s, it has subsequently played a central role in characterizing electroencephalographic activity observed in cognition and behavior. To date two broad explanatory approaches have emerged to account for this electrocortical phenomenon: (1) the direct (feedforward) oscillatory pacing of cortex from either thalamus or endogenously oscillatory populations of cortical neurons and (2) emergence through reverberant activity generated by the reciprocal (feedforward and feedback) interaction of populations of cortical and thalamic neurons. While representations of both approaches can be achieved by the computational modeling of individual populations of spike-based neurons, the latter approach when conceived using a coupled population-based method results

in mathematically compact formulations that are able to retain significant physiological detail.

As previously mentioned, Lopes da Silva et al. (1974) developed a population-based model of the alpha rhythm on the basis of the reciprocal coupling of excitatory and inhibitory neuronal populations. In the linearized model, by parameterizing the respective postsynaptic potentials according to the “fast” synaptic kinetics of inhibitory GABA and excitatory AMPA/kainate ionotropic receptor activity, alpha band resonances (damped poles of the electrocortical transfer function) emerged. Thus, in response to an impulse input $P(t) = \delta(t)$, damped sinusoidal behavior would result, thereby serving as a model for time-locked evoked electrocortical activity. In response to broadband white noise driving $|P(f)|^2$ is constant and a peaked power spectrum, for physiologically plausible values of the population coupling strength K , is obtained. This model was subsequently extended by Jansen and Rit (1995), by the addition of a feedback population of excitatory neurons, in order to account for the visual evoked potential.

In contrast to this approach, a number of neural population models have been developed that produce deterministic and noise-driven alpha band activity by the coupling of populations of thalamocortical (Robinson et al. 2002) and cortical inhibitory neurons (Bojak and Liley 2005; Liley et al. 2002). Figure 3 illustrates the linearized noise spectra of three important neural population models that have been developed to explain resting alpha band EEG activity.

Epilepsy, Anesthesia, Sleep, and Inferential Neuroimaging

Because neural population models aim to describe macroscopic level properties, they are consequently well placed to describe macroscopic level perturbations that attend alterations in brain function as occurring during sleep, anesthesia, and disease states such as epilepsy.

Epilepsy is characterized by the sudden occurrence of hyper-synchronous firing activity within relatively large populations of neurons and is thus amenable to being dynamically described by state changes in appropriately constructed neural

Neural Population Model, Fig. 3 White noise fluctuation spectra of three prominent neural population models that produce alpha (8–13 Hz) band model electroencephalographic activity. *Top* – model of Lopes da Silva et al. (1974) for various values of K (see Eq. 30). *Middle* – model of Robinson et al. (2002) fitted to a single subject’s eyes-

population models (see entry ► “Epilepsy, Neural Population Models of”). A typical approach is to consider coupled populations of excitatory and inhibitory neurons and to systematically investigate the onset of limit-cycle oscillations through either physiologically motivated parametric perturbations (bifurcations), noise-driven transitions between stable attractors that correspond to normal and seizure states (multistability), or a combination of the two. On this basis it has been hypothesized that variations in the shape of the boundary between normal and seizure states and the magnitude of noise-driven resting fluctuations may account for many of the dynamical features seen in focal and generalized epilepsies (Lytton 2008).

During the progression to deep anesthesia, the EEG undergoes a sequence of reasonably well-defined quantitative changes. The majority of clinically used anesthetic agents, at increasing concentrations, progressively decrease the median EEG frequency until the onset of burst suppression – quasiperiodic alternations of high-amplitude and isoelectric EEG activity. Modeling the large-scale electrophysiological effects of anesthetic agents using a neural population formalism, based on the parametric incorporation of empirically identified cellular and molecular targets, may provide an important mesoscopic explanatory bridge linking the microscopic sites of drug action with their large-scale macroscopic effects (Foster et al. 2008). On this basis a range of neural population models have been developed to account for the effects of anesthetics on the EEG (see entry ► “Anesthesia, Neural Population Models of”) by assuming that they selectively prolong the decay phase of the unitary inhibitory postsynaptic potential (see Fig. 2).

Sleep and anesthesia share a number of important features. Both are associated with unconsciousness and reduced cerebral metabolism and, at modest anesthetic levels, share similar EEG

◀ **Neural Population Model, Fig. 3** (continued) closed resting EEG. *Bottom* – model of Liley et al. (2002) for a range of parameter sets exhibiting spectrally plausible eyes-closed EEG. (All figures reproduced with permission)

patterns such as spindles, K-complexes, and delta waves. However, there appear to be important differences, particularly in the role that subcortical neuromodulatory systems have in modulating cortical activity. Neural population models of sleep have therefore been developed in an attempt to resolve the mechanistic differences between natural sleep and anesthesia (see entry ► [“Sleep, Neural Population Models of”](#)). To date two broad approaches have emerged (Sleigh et al. 2011). In the first it is assumed that brain stem neuromodulatory control is preeminent with cortical responses “slaved” to the output of the subcortical systems. In the second approach, subcortical neuromodulatory systems are not explicitly modeled, but instead their effects are incorporated as parametric modifications of a cortical or thalamocortical level neural population model.

An emerging application of neural population models is in inferencing from neuroimaging data to functional connectivity. Important in this regard is the Bayesian-based fitting of the Jansen and Rit model to stimulus-evoked EEG, known as dynamic causal modeling (DCM) (Moran et al. 2009; see entry ► [“Dynamic Causal Modelling with Neural Population Models”](#)). In this approach a set of competing hypotheses are formulated regarding the architecture of connectivity between neural populations. Model comparison and selection depends on a Bayesian evaluation of how well a given model m explains the observed data y , i.e., $p(y|m)$ is defined as the probability of observing data y given model topology m .

Definition

neuroConstruct (<http://www.neuroConstruct.org>, Gleeson et al. 2007) is a software application designed to facilitate the creation of complex networks of biophysically detailed neurons in 3D through a graphical user interface. It automatically generates scripts for a number of popular neuronal simulators, allowing the modeler to concentrate on incorporating and analyzing the anatomical and physiological aspects of the model, rather than learning a simulator specific programming language.

Detailed Description

Key Features

Generation of 3D Networks of Cells neuroConstruct was initially developed to allow generation of complex networks of anatomically detailed cells, to help understand the functioning of intricately connected microcircuits in brain regions such as the cerebellum and cerebral cortex. Prototype cells can be created for the neurons known to be present, with 3D representations of

dendrites and axons. Populations of these cells can be placed in regions in space, reflecting known cell densities and anatomical arrangements. Synaptic connectivity can then be generated based on rules for numbers of connections between pairs of cells, specific subregions of the cells to target, and the dynamical models to use for synaptic connections.

Simulator-Independent Specification of Multi-compartmental Spiking Cell Models

Cell models incorporating realistic morphologies along with known distributions of active membrane currents are important tools in helping to understand the physiological basis for cell spiking properties as well as synaptic integration in complex neurons. Multiple simulators (e.g., NEURON, GENESIS) support these types of cell models but normally have their own ways to specify the structure and biophysical properties of the cells. neuroConstruct allows users to create such cell models through the graphical interface which can then be mapped onto multiple simulator specific formats for executing the model. This is achieved through support for cross simulator standards (such as NeuroML, see below) and the ability to import various model elements, such as reconstructed neuronal morphologies (e.g., traced with Neurolucida) into neuroConstruct's internal format.

Automated Code Generation for Multiple Simulators

Neuronal simulators like NEURON, GENESIS, MOOSE, and PSICS have their own native formats for describing the structure of cells, ion channel, and synapse models, for controlling simulations and plotting/saving the generated data. Learning these simulator specific languages can be a big barrier to use of such simulators. neuroConstruct can translate its internal representation of cells and networks into scripts specific for a number of simulators, including the above named ones, as well as generating scripts for PyNN, a Python-based, cross simulator format which is currently supported by NEURON, NEST, and Brian. Note that not every type of model supported by neuroConstruct can be run across all simulators, see table below for more details.

Simulators supported by neuroConstruct

Simulator	Types of models supported
NEURON	Multicompartmental, conductance-based neurons and networks
GENESIS	Multicompartmental, conductance-based neurons and networks
MOOSE	Multicompartmental, conductance-based neurons and networks
PSICS	Single (multicompartmental, conductance-based) neuron models
PyNN	Large-scale networks of abstract/single compartment cells

Visualization and Analysis of Network Activity

When a simulation is run on one of the above platforms supported by neuroConstruct, the data generated is saved in a common format across simulators (either in simple text files or a standard binary format, HDF5). This simulation data can be loaded back into neuroConstruct along with the generated network structure. The cell spiking behavior can be visualized, and there are various options available through the graphical interface for analyzing cells and network activity, including plotting of single cell membrane potential traces, raster plots, population activity histograms, etc.

Import and Export of NeuroML neuroConstruct was created in parallel with the development of NeuroML, a simulator-independent language for describing biophysically detailed neuronal and network models (Gleeson et al. 2010). There are a number of options in neuroConstruct for importing model elements (morphologies, ion channels, synapses, or network structure) in NeuroML format, and all networks generated by neuroConstruct can be exported in NeuroML format (both the stable, widely used 1.8.1 version and the 2.0 version which is in active development, see below).

Recent Work

Python Interface Interacting with a model through a graphical interface is useful for model construction and testing, but once the model is ready to be used for addressing a research question, it is often the case that many simulations will need to be run, usually with a small modification

to the model between each simulation. For this purpose a Python scripting interface has been added to neuroConstruct, allowing full access to all features of the application (loading projects, changing any parameters, and generating networks and simulation code) from a script file. This allows neuroConstruct to be integrated into a larger toolchain using Python for model construction, refinement, validation, and analysis.

Support for Parallel Simulations NEURON has recently added support for running simulations across multiple processors, from a single machine with multiple cores up to parallel supercomputing clusters. neuroConstruct has added features to specify the target parallel computing environment and generate the appropriate NEURON scripts for execution either on the local machine or on a remote computing resource.

Interaction with NeuroML 2 The latest version of NeuroML, v2.0, is based on a new language for describing the behavior of dynamical models in a hierarchical manner (LEMS, the Low Entropy Model Specification language), allowing greater extensibility in the types of models which are supported by NeuroML. neuroConstruct supports cells and channel/synapses specified in this format. The machine readable nature of LEMS also facilitates mapping to and from other structured formats (e.g., SBML, which is widely used in the Systems Biology community) and so will help to widen the range of model types supported by neuroConstruct and the types of simulators on which the models can be executed.

Availability

neuroConstruct is written in Java, allowing it to be used across multiple operating systems. The application is freely available for download from <http://www.neuroconstruct.org/download>, and there are binary installers available for Windows, Linux, and Mac OS. The source code for neuroConstruct is also available under the GNU General Public License. It is currently being developed on GitHub at <https://github.com/NeuralEnsemble/neuroConstruct>.

Definition

The NeuroElectro Project is an effort to curate data about the electrophysiological properties of neurons. It contains experimental data extracted from the literature about dozens of basic properties (such as resting membrane potential, action

potential width, etc.) for hundreds of distinct types of neurons. It can be browsed online at <http://neuroelectro.org>.

Detailed Description

Computational neuroscientists have argued that the electrophysiological properties of neurons determine their computational roles. Furthermore, models containing or concerning neurons can be constrained or validated in part using empirical data on single-cell electrophysiology. However, compared with imaging or genetic data, these data are infrequently published in a format that permits them to be easily discovered in the literature. The NeuroElectro Project (<http://neuroelectro.org>, Tripathy et al. 2014) solves this problem by providing a database on the electrophysiological diversity of mammalian neuron types.

Implementation

This database is populated primarily using automated text extraction from tables of journal articles using Python. A subset of records have been manually validated against the primary literature. Neuron types are identified using the listing of neuron types provided by NeuroLex ((Larson and Martone 2013; Hamilton et al. 2012), <http://neurolex.org>); electrophysiological property types are identified using a custom ontology which formalizes existing community standards (Ascoli et al. 2008).

Data Provenance

While NeuroElectro contains information about 27 distinct electrophysiological properties, those most heavily represented include resting membrane potential, input resistance, action potential height and width, etc. The list of journals containing the source information includes those from the Elsevier, HighWire, Wiley, and Oxford family of journals, including The Journal of Neuroscience, The Journal of Physiology, and The Journal of Neurophysiology, among others.

NeuroElectro also contains details on each study experimental condition (like species or electrode-type used), the so-called metadata, obtained using similar text extraction techniques applied to article methods sections.

Participation

The NeuroElectro web interface (<http://neuroelectro.org>) also invites users to contribute to the database content. For example, users can suggest relevant articles on a specific neuron type as well as validate content that has been extracted via the automated algorithms. Furthermore, users can elect to become “content experts” on a specific neuron type and can then modify the database content directly.

Scientific Goals

NeuroElectro also contains analyses of the resulting database, yielding novel relationships on the electrophysiological similarity of different neuron types throughout the brain. Among these are hierarchical classifications of neuron types based on similarity of electrophysiological properties. The project maintainers are also aiming to relate gene expression patterns in specific cell types to those cells’ electrophysiological properties, using expression data obtained through the Allen Brain Atlas ((Lein et al. 2007), <http://brain-map.org>).

Neurofitter is a software tool developed to enable computational neuroscientists to tune the parameters of a neuron model. The constraints on the

model are given in the form of intracellular voltage traces recorded during stimulus protocols. The parameters are in general the maximal conductances of the ion channels in the model. Neurofitter uses global optimization methods to find the parameter values that minimize the differences in the phase-plane trajectory density plot between the target voltage traces and the voltage traces generated by the neuron model.

Detailed Description

Background

Due to improvements in experimental techniques and computational power available to neuroscientists, over the years, neuron models have become more and more complex. One manifestation of this complexity is the number of parameters used in these models. Unfortunately, it is not always possible to experimentally determine exact values for all these parameters. Especially, the maximal conductances of all the ion channels in a complex morphology tend to be unknown factors.

Traditionally, neuroscientists tried to overcome this limitation by tuning these unknown model parameters by hand. This can however be a tedious task and has the risk of introducing biases. To automate the fitting of parameters, software tools have been developed by several research groups. Neurofitter (Van Geit et al. 2007) was originally designed to help with the development of a cerebellar Purkinje cell model. The complex morphology of the dendrites of this type of cell, together with its elaborate calcium dynamics, makes it difficult to tune its parameters.

Method

When solving an optimization problem, one important aspect is the choice of the fitness function that evaluates for every parameter set how good or bad the solution is. For the problem Neurofitter tries to solve, the fitness function has to compare the similarity between two voltage traces. A naïve implementation would calculate the root-mean-square (RMS) error between the two voltage traces. Unfortunately, when neurons are repeatedly stimulated with the same protocol, their responses mostly do

not overlap exactly. Using the RMS error would punish a small time shift between traces with a very bad fitness value, which is undesirable. To overcome this problem, Neurofitter makes use of the phase-plane trajectory density method (LeMasson and Maex 2001). The data is plotted as voltage against the time derivative of the voltage and binned by a two-dimensional grid (Fig. 1).

The method then compares the number of points in every bin between the two voltage traces to calculate an error value:

$$\text{Error} = \sqrt{\sum_{i=1}^{N_x} \sum_{j=1}^{N_y} \left(\frac{\text{Target}_{ij}}{N_{\text{target}}} - \frac{\text{Model}_{ij}}{N_{\text{model}}} \right)^2}$$

with Target_{ij} and Model_{ij} being the number of points in a bin in the V - dV/dt plot of the target and model voltage traces, respectively. N_x and N_y are the number of bins of the grid in the x and y direction. The error measures of several traces can be combined by calculating a weighted sum or, in case multi-objective optimization methods are used, the error value of every trace can be defined as a separate objective.

By comparing in this way the different traces generated by the model and the target data, Neurofitter can generate a fitness value for every parameter set that determines how good the model, using these parameter values, is able to replicate the target data. Global optimization techniques, like, e.g., evolutionary algorithms, are then used by the software to find the set of parameter values that maximizes the fitness function.

Although the nature of this error measure puts a lot of emphasis on the shape of the action potential, studies like Achard and De Schutter 2006, show that the method can create models that also match firing frequencies, resting membrane potentials, etc.

Software Implementation

The software is written in C++. It interacts with neuron simulators using a file-based protocol, which allows the user to choose between a wide range of simulators like, e.g., Neuron (Hines and Carnevale 1997) and Genesis (Bower and Beeman 1998). Since fitness evaluations in the optimization algorithms are in general

Neurofitter, Fig. 1 Voltage trace recorded from a Purkinje cell model and the corresponding phase-plane trajectory plot (grid bins in *grey*)

embarrassingly parallel, Neurofitter has the ability to farm out these evaluations on cluster computers using the Message Passing Interface (Nagle 2005). Because the code does not have many external dependencies, it should run on most Unix-like operating systems that have an MPI package and neuron simulator installed.

Some global optimization techniques like evolutionary algorithms, particle swarm optimization, random search, etc., are already built into Neurofitter, but the user can easily link to external libraries or self-implemented search algorithms.

The software is configured using an XML file. In this file, the user can specify which

optimization algorithm to use, the number of parameters, the parameter ranges, etc.

The code is available at <http://neurofitter.sourceforge.net> and <http://github.com/tclose/NeuroFitter>.

Applications

The Neurofitter method was used in several studies including a parameter analysis of a Purkinje cell model (Achard and De Schutter 2006), the fitting of a two-dimensional pattern generator model (Van Geit et al. 2007) and to find the parameters of a calcium model (Anwar et al. 2012).

Definition

Neuroimaging denotes measurements of the brain with sufficient spatial resolution to construct maps of anatomy (structural neuroimaging) and activity (functional neuroimaging), respectively. Where a functional neuroimaging modality can capture spatial snapshots at sufficient speed, its data can be used to infer spatiotemporal brain dynamics. The spatial resolution of noninvasive functional neuroimaging in humans is limited to about one millimeter and requires the coherent activity of a large number of neurons to generate a signal that exceeds the noise floor. This is an ideal match for neural population models (NPMs), which are designed to capture the mass activity of neural groupings at mesoscopic scales and above. However, in order to compare NPM predictions to neuroimaging data, one also has to include signal expression – a measurement function – that maps the NPM-generated activity onto the sensor recordings. For most popular neuroimaging modalities, including multimodal approaches, such forward modelling “pipelines” are now available and have been used to predict and analyze data.

Detailed Description

Functional neuroimaging encompasses a wide variety of methods to detect and quantify brain activity (Bandettini 2009; Friston 2002; Horwitz et al. 2000). The most popular methods today are perhaps electro- and magnetoencephalography (EEG and MEG) (Hansen et al. 2010; Michel and Murray 2012; Niedermeyer and Lopes da Silva 2005; Salmelin and Baillet 2009) and functional magnetic resonance imaging (fMRI) (Buxton 2009; Huettel et al. 2008; Logothetis 2008; Ramsey et al. 2002), respectively. A wide variety of other methods exist, for example, positron-emission tomography (PET) (Bailey et al. 2005; Valk et al. 2006), voltage-sensitive dye imaging (VSDi) (Chemla and Chavane 2010; Grinvald and Hildesheim 2004), and functional near-infrared spectroscopy (fNIRS) (Bunce

et al. 2006; Ferrari and Quaresima 2012; Villringer et al. 1993). One can make a conceptual distinction between neuroimaging and methods that directly record the activity of individual neurons, like patch clamping. However, this boundary is somewhat fluid, raising, for example, the question of whether measurements obtained with a multielectrode array (MEA) (Bakker et al. 2009; Buzsaki 2004; Taketani and Baudry 2006) belong to the category of neuroimaging or electrophysiology. Here we take the view that the “imaging” aspect indicates an ability to map out, at least in principle, spatially distributed activity. This almost invariably requires processing of the recorded raw data before an actual spatial image can be constructed for visualization, i.e., even fNIRS, which uses light, does not literally take a picture of brain activity. Inference from such data usually relies on statistical maps of signal variance, not on the signals themselves (Friston et al. 1991). It is also true that often the spatial aspect does not play a role in neuroimaging applications, e.g., research might concentrate merely on the temporal EEG patterns recorded from a single EEG electrode. However, we will consider a method to be “neuroimaging” if it easily allows and/or is commonly used for spatial activity mapping.

A further distinction can be made between invasive and noninvasive methods. We will focus here on noninvasive methods, simply because for ethical reasons these are typically the only ones available for the study of human brain activity. Invasive neuroimaging of humans primarily occurs during surgical treatment of epilepsy, where electrocorticograms (ECoG) can be recorded (Foster et al. 2012; Jerbi et al. 2009; Lee et al. 2013). The ECoG is, however, sufficiently similar to EEG to not require a separate discussion here. Furthermore, we will focus on discussing EEG/MEG and fMRI. On one hand, this reflects the preference of current studies, both experimental and theoretical. On the other hand, these methods can be considered as representative of two distinct classes of neuroimaging: EEG/MEG reflects electrophysiological activity. In contrast, fMRI is sensitive to metabolic and hemodynamic

responses to neural activity (Aquino et al. 2012; Shibasaki 2008). Other methods can be classified accordingly, for example, VSDI is an electrophysiological measurement whereas PET is a metabolic-hemodynamic one. In consequence, modelling concepts and methods developed for the leading modalities EEG/MEG and fMRI usually translate straightforwardly to other neuroimaging techniques of the same respective class. Furthermore, EEG and fMRI can be recorded concurrently (Huster et al. 2012; Laufs et al. 2008; Mulert and Lemieux 2010; Ullsperger and Debener 2010). This is particularly attractive for the currently very active field of multimodal neuroimaging (Biessmann et al. 2011; Blinowska et al. 2009; Freeman et al. 2009; Mulert et al. 2008; Stufflebeam and Rosen 2007), since simultaneous recordings avoid the problem of potentially different brain states in spite of the same external setting (e.g., executing the same task). Once more we can expect that modelling and data analysis methods now being developed for the EEG and fMRI case of (Nguyen et al. 2013) will become the basis for the integration of other neuroimaging modalities. Finally, EEG/MEG and fMRI are naturally complementary, as detailed in Table 1. This makes them attractive from both a modelling and a data analysis perspective as extreme test cases for a unified description. In the following we will hence focus on EEG/MEG

Neuroimaging, Neural Population Models for,
Table 1 Comparison of EEG/MEG and fMRI

	EEG/MEG	fMRI
Spatial resolution	>1 cm	>0.5 mm
Temporal resolution	~1 ms	>1 s
Brain coverage	Gyri/sulci	All
Source to signal	Direct, electrophysiological	Indirect, metabolic-hemodynamic
Signal type	Surface measure	Volume measure
Signal generation	Unclear	Unclear
Costs	Cheap/expensive	Expensive

and fMRI, although the same principles apply to other functional neuroimaging modalities.

Spatial Resolution of Neuroimaging and Coherent Activity

NPMs do not describe the activity of individual neurons but the collective activity of many. We can connect this kind of description directly to the experimental constraints of neuroimaging if we assume that the population of neurons we describe with such models is *localized*. Thus, the individual neurons that make up the population are not spatially dispersed across the brain, as they could be, but rather are located in a circumscribed region of the brain. Furthermore, we assume that this localization is compact, i.e., ideally all individual neurons within the population's region are in fact part of it, and none outside are.

The spatial resolution of a functional neuroimaging modality indicates to what extent we can separate the signal generated by different circumscribed regions of the brain. Basically, the actual spatial geometry of the brain gets parcelled into “source regions” expressing distinct outputs: it is from these that we form an “image” of brain activity. For example, fMRI acquires data from “voxels,” cuboids parcellating the brain volume. If the NPM describes the neural sources of this signal and if we assign populations according to the spatial separation of signals in the neuroimaging modality or at even smaller scales (Breakspear and Terry 2002), then the NPM can predict the recorded neuroimage. However, in practice this simple picture becomes more complicated. For example, experimentally there is signal distortion between different fMRI voxels (Jezzard and Clare 1999; Weiskopf et al. 2006), compromising the idea of a clean separation into signal regions. Or on the theoretical side, the NPM might be based upon a continuum approximation (Coombes 2010; Liley et al. 2012), in which case the predicted signal could derive from an average over the designated source region, with the underlying field values possibly being quite inhomogeneous across this region. Nevertheless, it remains

useful to connect the spatial resolution of a neuroimaging modality to a conceptual “population size” of the NPM if one uses the NPM as model for the recorded signals. More detailed technical considerations of continuum versus discrete NPMs are provided in other entries; here, we concern ourselves primarily with their practical use in providing generative models of functional neuroimaging data.

The maximum spatial resolution of current functional neuroimaging is about 0.1 mm; cf. Fig. 1. For noninvasive techniques it is about 1 mm. At the anatomical level, this scale corresponds roughly to the lateral extent of a macrocolumn (0.5–3 mm) and the vertical depth of a few layers (6 canonical layers in 2–5 mm cortical thickness). The actual number of neurons that actively contribute to each part of a maximally resolved neuroimage is difficult to determine. However, if we take the total number of neurons in the mentioned anatomical structures as a proxy, then the number of neurons participating directly (as sources) or indirectly (influencing the sources) in the signal generation will be in the hundreds of thousands for fMRI and in the order of millions for EEG. It is these large numbers that make a description in terms of NPMs, rather than individual cell models, attractive.

There is a second consideration that motivates the use of NPMs as a model for neuroimaging signals, namely, that of coherent activity. We know from theoretical studies that strongly coupled neural systems typically start to exhibit coherent activity, i.e., the neurons start to align their activity patterns and fire together (Breakspear et al. 2003). We also know that the neurons are strongly connected at the anatomical size levels discussed above. For example, the lateral extent of a macrocolumn is given by the reach of horizontal short-range connectivity (Mountcastle 1997). It is hence reasonable to expect coherent activity in the millimeter range, and this has been confirmed experimentally (Bullock et al. 1995).

We can now make a conceptual argument: assume N sources that produce an oscillatory signal $S_i = A_i \sin(\omega t + \varphi_i)$, where for simplicity all of them have the same frequency. Then the sum of all

Neuroimaging, Neural Population Models for,

Fig. 1 Temporal and spatial scales of various neuroimaging modalities and other techniques for recording neural activity

these signals $S \equiv \sum_{i=1}^N S_i = A \sin(\omega t + \varphi)$, and the amplitude is given by $A^2 = \sum_{i=1}^N A_i^2 + 2 \sum_{i=1}^N \sum_{j>i}^N A_i A_j \cos(\varphi_i - \varphi_j)$. If all phases are equal, then the cosine becomes one and we have $A = \sqrt{\left(\sum_{i=1}^N A_i\right)^2}$. But if the phases are random with uniform distribution on $(0, 2\pi)$, then the expected value will be $E[A] = \sqrt{\sum_{i=1}^N A_i^2}$, since the expected value of the cosine becomes zero. The difference becomes obvious if we consider the case where all $A_i = A_0$, then for coherent activity $A = N A_0$, but for random activity $E[A] = \sqrt{N} A_0$. Thus, in essence the signal of coherent activity grows linearly with the number of sources but the signal of entirely incoherent (random) activity only with the square root of the number of sources (Nunez and Srinivasan 2006). In consequence, a thousand coherently active neurons can produce a signal that rivals the expected signal of a million incoherently active neurons.

We have seen that NPMs created for describing neuroimaging describe regions of the brain parcelled out by the modality that contains a large number of neurons and that strong anatomical connections between these lead to coherent activity in these regions that is both theoretically expected and experimentally observed. We can

hence conclude that NPMs primarily (and as spatial resolution decreases, exclusively) model the *coherent* signal generation within the regions parcelled out by the functional imaging modality. Hence, the neural populations in such models should be understood as effectively representing not *all* neurons (of a specific type), but rather only those directly or indirectly involved in generating coherent activity. This point is not always appreciated in the literature. For example, if an NPM predicts very little activity for a population of pyramidal neurons involved in generating a neuroimaging signal, then patch-clamp measurements of individual neurons showing high firing rates do not necessarily contradict this. Rather one would have to check whether such firing is also coherent across the entire region. If it is incoherent, then it simply does not feature dominantly in the NPM. Finally, we note that the mathematical approach of deriving NPMs from individual cell models by keeping only the first few moments of a population density (Brunel and Wang 2001) neatly parallels our argument above from signal strength. Essentially the mean captures the expected signal intensity, whereas the variance captures the dispersion of those states, which also plays an important role in shaping NPMs (Marreiros et al. 2008).

Head Geometry, Brain Connectivity, and Signal Expression

There are essentially three levels of modelling the anatomical and physiological substrate of the NPMs in neuroimaging. At the most basic level, one focuses on a single neural population, or perhaps on a few that are connected, but without mapping out the location of the sources or employing a spatial representation of the brain connectivity. A typical example for this is the Jansen-Rit model (Jansen and Rit 1995). This kind of model is suitable for investigating basic intrinsic dynamics and studying gross extrinsic influences that either act to some extent indiscriminately across the brain (e.g., psychoactive drugs) or where a localized description is sufficient (e.g., a seizure confined predominantly to one region). At an intermediate level, the spatial distribution of sources and brain connectivity can be introduced in a simplified manner that represents a trade-off between tractable mathematics and biological realism. Since the cortical gray matter is sheet-like (in humans 2–5 mm radial depth but with 0.2 m² horizontal area), usually a representation as two-dimensional surface is chosen. Often this surface is realized as a square grid to accommodate numerical computation. Most authors also limit brain connectivity to the “background connectivity” (Hellwig 2000; Kaiser et al. 2009; Liley and Wright 1994; Robinson et al. 1997) of the brain, which is compatible with assumptions of homogeneity and isotropy. In this case one can simulate the spread of activity with a partial differential equation (PDE), which is convenient both for analytical and for numerical reasons (Griffith 1963, 1965; Jirsa and Haken 1996; Liley et al. 2002; Robinson et al. 1997). Finally, the signal expression is typically simplistic. Usually the measured signal is considered to be directly proportional to some model variable, perhaps including some averaging over a region to represent the spatial resolution of the neuroimaging modality (Bojak and Liley 2005).

Models making these simplifications can be used to describe certain spatial features of brain activity, e.g., various features of “brain waves” (Bojak and Liley 2007; Robinson et al. 2002;

Wu et al. 2008) or power spectra predictions taking spatial effects into account (Bojak et al. 2004; Bojak and Liley 2005; Robinson et al. 2001), as illustrated in Fig. 2. At the cost of greater numerical effort, it is also possible to describe anisotropic connectivity with the convenient PDE approach, which is, for example, important in the visual cortex (Bojak and Liley 2010; Coombes et al. 2007; Pinotsis et al. 2013; Robinson 2006). Furthermore, we have so far focused our discussion on the cortex. However, the potential importance of (reciprocal) connectivity between the cortex and the subcortical structures cannot be overstated. Models that only include the cortex de facto subsume the influence of the subcortical structures into an effective description of the cortical neural population, much as, for example, the omission of an explicit model for the glia in the cortex does not indicate a denial of their potential influence on the neural dynamics. However, for certain brain phenomena, it will doubtlessly be the case that explicit modelling of the subcortical structures is required. Some authors argue that the corticothalamic feedback is crucial even for the common alpha rhythm, while others see it as a cortical resonance merely excited by the thalamus (Freyer et al. 2011, 2012; Liley et al. 2002, 2010; Robinson et al. 2001). It is difficult to decide between such competing theoretical models if direct experimental evidence is ambiguous and the models are complex enough to fit available data. Here we need to keep Einstein’s razor in mind: “Everything should be made as simple as possible, but no simpler.” The mere existence of further anatomical and physiological detail does not mean that it has to be included. In practice it may be better to simplify the model if the task at hand does not require that detail. However, if either the data speak to this detail or the need to interpret the model meaningfully requires it, then we should include it. For example, it cannot be doubted that a proper description of Parkinsonism requires the inclusion of the basal ganglia and the thalamus (van Albada and Robinson 2009; van Albada et al. 2009). Furthermore, in principle one would always wish to find a unifying, single model that can fit and predict multiple phenomena (Breakspear et al. 2006).

Neuroimaging, Neural Population Models for, Fig. 2 Excitatory mean soma membrane potential h_e of a Liley model evaluated on a 512×512 grid representing $(51.2 \text{ cm})^2$ of flattened-out cortex; variations by about 3 mV peak to trough are shown by height and color. The EEG was assumed to be linearly proportional to h_e . Nine

consecutive system states are shown with relative timings as indicated. The calculation is described in more detail in Bojak et al. (2004). Shown here is the case with a 7 m/s conduction velocity in the process of spontaneously developing an α -rhythm of 10.7 Hz with a radial wavelength of 17.1 cm

N

A third level of modelling employs anatomically and physiologically accurate representations of the cortex, potentially of the subcortical structures, and of the surrounding head structure as needed for realistic signal expression (Bojak et al. 2011; Jirsa et al. 2002; Riera et al. 2005, 2013; Sotero et al. 2007). The first step here is to obtain structural MRI data, which can be used to distinguish different tissue types. If one is interested purely in metabolic-hemodynamic signals like fMRI, then it is sufficient to model the system parcellated into these voxels, e.g., by assigning neural populations to gray matter voxels. However, as we will discuss modelling of electrophysiological signals like EEG/MEG relies on spatially oriented dipole sources. Their

orientation is essentially perpendicular to the pial surface, hence one must add to the voxels an estimate of surface normals. Furthermore, electromagnetic signals suffer from volume conduction effects as the signal passes through tissues with different conductivities. For magnetic signals (e.g., MEG), the resulting distortions and spreading of the signal can be approximated well with a simple spherical model (Huang et al. 1999). However, for electrical signals the structure and conductivity of the head volume play a significant role. Hence, to realistically express electrophysiological signals, one must further process the structural MRI data suitably for orienting the sources and computing volume conduction. Volume conduction can be calculated in the

quasi-static approximation of Maxwell's equations (Sarvas 1987). The so-called boundary element method (BEM) assumes compartments wherein the conductivity is constant and isotropic (de Munck 1992; Oostendorp and van Oosterom 1989; Oostendorp et al. 2000) and requires the discretization of their surfaces, typically as a triangular mesh. The so-called finite element method (FEM) does not require such assumptions (Drechsler et al. 2009; Wagner et al. 2014; Yan et al. 1991), but requires the discretization of the entire volume, typically as a tetrahedral or hexahedral mesh. Figure 3 gives an impression of such mesh discretizations. While these methods are technically complex, their final result is usually delivered in a simple transfer matrix form: $\vec{\varphi}(t) = \mathbf{T} \cdot \vec{d}(t)$, where $\vec{d}$ is an N -dimensional vector of N sources, for example, N -oriented dipoles derived from NPM activity in a source region; $\vec{\varphi}$ is an M -dimensional vector of M recorded signals, for example, the potentials measured by M scalp electrodes; and $\mathbf{T}$ is an $M \times N$ -dimensional transfer matrix for the volume

conduction. Note that $\mathbf{T}$ is considered to be time-independent at least for the duration of the recording, i.e., structural changes that significantly impact signal expression typically require more time than is being recorded.

A growing number of open-source and commercial software tools exist for automatic MRI tissue segmentation, including FreeSurfer (Dale et al. 1999; Fischl et al. 1999), BrainSuite (Shattuck and Leahy 2002), BrainVISA (Rivière et al. 2003), FSL (Smith et al. 2004), SPM8 "New Segmentation" (Ashburner and Friston 2005; Weiskopf et al. 2011), CIVET (Kim et al. 2005), ITK-SNAP (Yushkevich et al. 2006), NFT (Acar and Makeig 2010), Atropos (Avants et al. 2011), FieldTrip (Oostenveld et al. 2011), ASA Pro (ANT Neuro BV, Enschede, Netherlands), CURRY Scan 7 (Compumedics NeuroScan, Charlotte, NC, USA), and BESA MRI 2.0/Research 6.0 (BESA GmbH, Gräfelfing, Germany). Mesh generation is included as well in some of the packages already mentioned, but can likewise be achieved with a variety of free and

Neuroimaging, Neural Population Models for,
Fig. 3 Mesh discretization of the head obtained from structural MRI. (a) Triangular surface meshes as appropriate for BEM. (b) Tetrahedral volume meshes as

appropriate for FEM. (Picture courtesy of Tom F. Oostendorp and Arno Janssen, Radboud University Nijmegen, the Netherlands)

proprietary software tools including DellIso (Dey and Levine 2008), Gmsh (Geuzaine and Remacle 2009), iso2mesh (Fang and Boas 2009), SimBio-Vgrid (Berti 2004), Abaqus/CAE (Dassault Systèmes, Vélizy-Villacoublay, France), COMSOL Multiphysics (COMSOL Ltd., Cambridge, UK), GiD (CIMNE, Barcelona, Spain), and ScanIP (Simpleware Ltd., Exeter, UK). One also needs electromagnetic forward solvers, which again are included in several of the initially mentioned packages. In addition we mention tools like Brainstorm (Tadel et al. 2011), MNE (Gramfort et al. 2014), OpenMEEG (Gramfort et al. 2010, 2011), and SimBio-NeuroFEM (Wolters et al. 2002). There also exists a complete open-source software pipeline for all these steps provided by ImageVis3D, Seg3D, BioMesh3D, and SCIRun (MacLeod et al. 2009).

In terms of connecting an NPM description to an obtained cortical surface, two basic numerical approaches are possible: on one hand, one can use simpler geometries for computation, e.g., representing each brain hemisphere by a sphere, and then deform these to obtain a prediction for the actual cortical surface (Jirsa et al. 2002). The simpler geometry will be covered with a regular mesh, and vertices there represent surrounding regular areas, which are then mapped to the convoluted cortical surface. However, this deformation will be nonconformal, thus changing relative distances between vertices on the cortical surface as compared to the simple geometry. Effectively, this leads to uncontrolled changes of the conduction velocity between vertices. On the other hand, one can directly use the extracted cortical surface and consider the mesh vertices as representing the surrounding neural tissue (Bojak et al. 2010, 2011). This does not distort the conduction velocity but is more complicated numerically since the vertices are not placed in a regular manner. The latter approach also can be used to connect gray matter voxels, if one does not extract a cortical surface first (Sotero and Trujillo-Barreto 2008).

Given any such spatial discretization of the cortex (or of the brain more generally), one can assign one NPM per vertex to represent the local dynamics. The total brain dynamics are then determined by potentially thousands of NPMs at

the vertices, which are, however, typically coupled. Since the NPM at one specific vertex represents the dynamics of the surrounding neural tissue, the NPM should describe any brain connectivity contained in this tissue. For a typical discretization with tightly spaced vertices, perhaps a few millimeters apart, this would mean inhibitory and “intrinsic” (superficial layer) excitatory connectivity within the gray matter. Conduction delays at this range are typically neglected in the NPM, although temporal filtering in the synaptic compartment can introduce an effective time delay. One can also introduce explicit couplings between the NPMs at different vertices. These would be representative of mid- to long-range connections through the white matter and, hence, should be exclusively excitatory. Figure 4a demonstrates the principle. Here the different colors of the vertices are supposed to indicate parts of the same cortical mesh with large spatial separation, i.e., different brain regions. Clearly the entire connectome of the brain can now be specified through four numbers per connection (blue arrows): number of the source vertex (colored red), number of the target vertex (colored green), delay until a signal arrives (thus fiber length is divided by conduction velocity), and coupling weight (some measure of the strength of synaptic impact at target). In addition, however, one likely has to distinguish different types of connections, e.g., there might be two identical fiber specifications but one attached to the inhibitory and one to the excitatory subgroup of the target NPM.

The late Rolf Kötter pioneered the usage of tracer-derived connectivity data from macaque monkey contained in the CoCoMac database (Bakker et al. 2012; Blumenfeld et al. 2013; Stephan et al. 2001) for these kinds of simulations (Deco et al. 2011; Honey et al. 2007). The necessary cross-species mapping was first performed coordinate-free with the so-called Regional Map (Kötter and Wanke 2005) but has been associated with a specific parcellation of the cortex (Bezdin et al. 2012); cf. Fig. 4c. The main rationale was that tractography based on diffusion MRI in humans (Johansen-Berg and Rushworth 2009), while in most ways equal or even superior to the

tracer studies in animals, can only show the existence of a connection between two brain regions but not in which direction the signal will flow. In spite of the uncertainties of cross-species mapping, which includes some insuperable mismatches (e.g., concerning the brain regions for speech), the resulting differences in causal influences basically mandate going beyond just diffusion MRI for modelling purposes. Rough estimates of fiber tracts and, hence, their length can be obtained from a white matter surface by estimating the minimal path through the volume as shown in Fig. 4b (Bojak et al. 2011). As noted above, connectivity modelling requires simply the delay of signal conduction between two spatial points. Given the considerable uncertainties that remain concerning the actual conduction velocity of specific fibers in the brain (Liley et al. 2010), such a rough estimate of fiber length may well be

sufficient in a practical sense. Finally, it should be noted that any brain region like the ones in Fig. 4c will typically comprise many vertices, but connectivity matrices are typically given only at the brain region level. Hence, modellers need to specify by what scheme they actually match the vertices in one region to those in the other region, given that they only have the overall information for connectivity between regions. The issue of calibrating all the various assumptions that flow into connectivity models remains in our opinion unresolved (Bojak et al. 2011).

Electrophysiological Signals: EEG, MEG, and VSDi

The genesis of EEG and MEG is comparatively well understood. We will first discuss the EEG

Neuroimaging, Neural Population Models for,
Fig. 4 (a) Illustration of the coupling between different mesh vertices representing different brain regions. (b) Examples of minimal path estimates of long-range fiber

lengths. (Bojak et al. 2011). (c) An example of parcellating the cortex into different brain regions with the Regional Map. (Bezgin et al. 2012; Kötter and Wanke 2005)

and then comment briefly on the differences between EEG and MEG. Furthermore, in the following we mean by EEG recordings with electrodes placed on the scalp, as opposed to similar recordings with subdural electrodes resting on the surface of the cortex (ECoG) or by microelectrodes inside the brain (local field potentials, LFPs). A key observation is that while the most prominent activity of neurons is the production of action potentials, short “spikes” of activity traveling along their axons, such spikes do not make an appreciable contribution to the EEG (or indeed the ECoG). Instead the EEG shows “waves” of activity with the vast bulk of EEG activity occurring at frequencies below about 100 Hz. Originally it was thought that EEG/ECoG waves arise as temporal envelope of spiking activity (Adrian and Matthews 1934). This hypothesis can be tested with differential recordings using two microelectrodes, which localize the source of the activity to the space between the microelectrodes. LFPs indeed show both spike and wave contributions. However, the wave signals remain present up to cellular distances of 30 μm (Elul 1962, 1971), indicating that the wave contribution stems directly from neurons.

In the meantime it has become clear that the wave contribution to LFPs, and thus the EEG, arises from synaptic activity (Buzsaki et al. 2012; Nunez and Srinivasan 2006). For example, an excitatory synaptic input in the apical dendrites leads to a local influx from the extracellular space of cations, a localized “sink.” This has to be compensated by a “return current,” a flow back from the intracellular to the extracellular space to restore electroneutrality. This return current leaks out across the membrane as the synaptic current is conducted to the soma, establishing distributed “sources” at a distance to the sink. For a pyramidal neuron, most of the membrane area allowing the leakage is found in the distal branching of the apical dendrites and in the soma and basal dendrites, respectively. Consequently, a significant part of these sources typically would be located around the soma, at considerable distance to the sink. A source and a sink separated by a distance establish a current dipole, and so to a reasonable approximation, the synaptic input creates a dipole

potential. Indeed, more generally, one can make a multipole expansion of any charge configuration, where the contribution of higher terms falls off much faster with distance. Given effective electro-neutrality, there will be no monopole (sink without source or vice versa) contribution. But other than for very special charge arrangements, unlikely in realistic physiological scenarios, there will be dipole contributions arising similarly to the example just given. At some distance from the neuron, these dipoles will dominate over higher multipole contributions. Thus, while the impact of synaptic inputs is quite complicated (Linden et al. 2010), they essentially establish a current dipole in the neuron (Nunez and Srinivasan 2006).

In Fig. 5 we demonstrate two key facts: First, roughly spherical interneurons, and in general any neural source-sink configuration that is mostly “closed,” will not appreciably influence the EEG directly. It is true that a single input will always create a dipole, which, while weaker at a distance due to small size, could theoretically contribute; see Fig. 5c. However, the number of synapses on a neuron in the human brain is on average about 30,000 (DeFelipe et al. 2002), and with awake spontaneous firing rates of 0.5–5 spikes/s (Barth and Poulet 2012), neurons are bombarded by tens of thousands of synaptic inputs per second (Shu et al. 2003). Thus, *in vivo* Fig. 5d is more realistic. Second, aligned batches of pyramidal neurons, and in general any neural source-sink configuration that is mostly “open,” extend the dipole spatially so that one can talk of a “dipole layer” that will basically determine the EEG directly; see Fig. 5e. This is not fundamentally changed by the addition of “closed” configurations like interneurons; see Fig. 5e.

We have discussed how coherent activity strongly dominates the EEG signal. We now see that such activity at a synaptic level is precisely what is needed to create dipole layers like those shown in Fig. 5e and f, since it will make the sources and sinks appear in a coordinated fashion, whereas incoherent activity would cause the sources and sinks to appear at different times, preventing the dipole field from becoming spatially extended. The only remaining question is

Neuroimaging, Neural Population Models for,
Fig. 5 (a) Large dipole representing a layer V pyramidal cell with one excitatory synaptic input to the apical dendrites (sink: “-” label, blue color) and return current from the soma (source: “+” label, red). Equipotential lines are shown in green, representative field lines in black. An ECoG electrode can be imagined at the top of the figure and would record the variations of the potential indicated by the (cut) equipotential lines if moved left to right. (b) As

in (a), but with multiple excitatory inputs to the apical dendrites and sources more realistically resembling the pyramidal cell morphology including basal dendrites. Note that the basic dipole field remains. (c) Small dipole representing an interneuron with one excitatory synaptic input to the roughly spherical dendrites. Note the weakness and lack of variation of the potential at the top of the figure. (d) As in (c), but with multiple excitatory inputs to the roughly spherical dendrites. The size of the charge

N

whether one finds in the real brain an arrangement of pyramidal neurons like the one shown in Fig. 5e and f. Perhaps unsurprisingly – given the ease with which EEG can be recorded – there are several structures like this in the brain. In particular, the cortical layer V neurons have very long dendritic arborizations, which basically align perpendicular to the pia (see Fig. 6). Coherent synaptic activity in layer V neurons is hence a strong

candidate for the bulk of the EEG signal. As discussed above, such activity would lead to the formation of dipole layers with mesoscopic extent, oriented perpendicular to the pia. These are then precisely the dipoles whose volume conduction we discussed above.

In current practice, the complexities of the synaptic activation are generally ignored in source modelling of the EEG. Instead, the excitatory

Neuroimaging, Neural Population Models for, Fig. 5

(continued) configuration has been enlarged to avoid visual crowding. This “closed” configuration could also represent a clump of pyramidal neurons. The field is largely contained. (e) An “open” configuration that could represent a number of aligned pyramidal cells with inputs

as in (a). We see the beginning of a spatially extended dipole layer. (f) As in (e), but adding an interneuron with multiple inputs as in (d). We see that the smaller and closed charge configuration does not significantly disturb the dipole layer

mean soma membrane potential is used as a proxy (Jansen and Rit 1995; Liley et al. 2002; Robinson et al. 1997). This quantity is computed from some form of sum of excitatory postsynaptic potentials (EPSPs) and inhibitory ones (IPSPs), where the latter contributes negatively, since they hyperpolarize the membrane. The concrete model can range from a simple “instantaneous” subtraction of EPSPs and IPSPs (Jansen and Rit 1995) to voltage-dependent weights representing Nernst potentials and additional membrane dynamics with a proper time constant (Liley et al. 2002). One can argue that for “dipole-friendly” neural sources, say the layer V neurons, and for a surface measurement of the LFP, say with an ECoG electrode, the following holds (Speckmann and Elger 2005): The LFP will be roughly proportional to the membrane potential, however, with different signs according to the type of input – excitatory synaptic input to the apical dendrites and inhibitory input to the soma/basal dendrites contribute *negatively* – whereas excitatory synaptic input to the soma/basal dendrites and inhibitory input to the apical dendrites contribute *positively*. Thus, the simplifying assumption commonly made in NPMs amounts to claiming that one of these signs dominates so that the effect of excitation and inhibition does not become confused in the summation. Typically one would assume here that the negative sign dominates, i.e., most excitation arrives in the apical dendrites and most inhibition in the soma or basal dendrites (Miller et al. 2010). However, there is clearly a scope here for improving biological fidelity in the future.

Having dealt with the EEG, we can discuss MEG quickly. If we consider the electric field lines in Fig. 5, they show us essentially the induced current flow. However, note that we have plotted the extracellular field. The intracellular, primary current in the simplest case, Fig. 5a, flows against the extracellular electric field line, i.e., cations travel from the sink in the apical dendrites straight down to the soma, whereas the extracellular, secondary (or return) current then flows from the source to the sink as shown by the extracellular electric field lines. Of course, the actual path of these currents would be modified by the morphology of the neuron and the

composition of extracellular space, respectively. Current flow induces magnetic fields, which circle the currents. In our Fig. 5, the magnetic field lines are located in the plane perpendicular to the page. The weak magnetic fields of a mesoscopic (dipole) source can be measured with highly sensitive SQUID magnetometers. This is the basis of the MEG signal, and it makes clear that the EEG and the MEG are essentially two different ways of observing the same physical process.

However, there are in practice some differences (Baillet et al. 2001). In particular, looking at Fig. 5a again, we see that there are potential differences both along the top and bottom of the panel, as well as along the sides. This means that theoretically, at least the EEG measuring the potential against a reference can pick up contributions that are either tangential (parallel to the skull, idealized as a sphere) or radial (perpendicular to the skull, idealized as a sphere). In practice, however, EEG sensitivity reduces quickly with distance from the electrode, and we have argued that the actual neural sources are perpendicular to the pia. Consequently the EEG primarily captures radial sources from the gyri, where the pia runs close to and parallel to the skull. However, there will be some contributions from where the pia folds away from the skull down into a sulcus, creating dipoles tangential to the skull but not too distant from the electrode. In contrast the MEG essentially detects only tangential dipoles (and since again the signal reduces quickly with depth, mostly the same tangential dipoles high up in the sulci that “interfere” with the EEG measurement). The reason is that the coil surfaces of the SQUID magnetometers in an MEG are usually arranged flush with the surface of a partial sphere placed around the head for recording. They can then only record radial magnetic fields. If a current dipole is radial (e.g., if we imagine in Fig. 5a that the pia is on the top), then its magnetic field is tangential and will not be seen in the MEG. That the EEG signal derives from radial sources “contaminated” by tangential ones, whereas the MEG only from tangential ones, explains in part why the MEG can achieve higher spatial localization than the EEG. In addition, the smearing of the EEG signal by volume

conduction is largely absent for MEG. However, MEG technology is orders of magnitude more expensive; hence, EEG continues to be more commonly used. As far as modelling is concerned, both signals are ultimately proportional to the same current dipole strength. However, recent efforts to reconstruct the functional connectivity of cortical oscillations have focused on MEG (Brookes et al. 2012; Hipp et al. 2012).

Voltage-sensitive dye (VSD) imaging (Chemla and Chavane 2010; Grinvald and Hildesheim 2004) is yet another method to basically measure the same underlying signal, if applied to sizable parts of the cortex. The basic principle here is that certain dyes bind to the cell membrane and change their absorbance, fluorescence, or birefringence in proportion to changes of the membrane potential. The other factor that determines the amount of light one can record is then simply the area of the membrane successfully stained with the dye. Since these dyes can be applied to the cortical surface and since by far the largest fraction of (unmyelinated) membrane available belongs to the dendritic arborizations, once again the synaptic input drives the signal. However, it is less clear which neural groups will contribute most to the VSD signal, making comparisons to EEG/MEG problematic. It should be noted though that while VSDs typically stain only superficial layers I–III, layer V pyramidal cells which we have identified as likely dominating EEG/MEG also have extensive dendritic trees in these layers. The optical resolution obtained from VSD light emissions is maximally about 0.5 μm , though the pixel size for large-scale recordings we are concerned with here is more in the 50 μm range, and the temporal resolution is in milliseconds or less, making this as superior modality where it can be applied (Roland et al. 2006). However, this is an invasive method *in vivo*, since one has to penetrate the skull to apply the dye and then observe the light, if one is not applying the VSD *in vitro* to a cortical slice or to cultured neurons anyhow. Some VSDs are also phototoxic and have lasting pharmacological effects. This basically excludes recordings from humans on ethical grounds. Finally, for large-scale recordings, a “macroscope” (a microscope with large numerical aperture at low magnification)

is required with windows in the millimeter to centimeter range.

Modelling VSDi with NPMs is still in its infancy. One can view the extensions of the “laterally interconnected synergetically self-organizing map (LISSOM)” model in (Sit and Miikkulainen 2007) as the construction of crude NPM. A neural field model containing three layers and six populations (Haeusler and Maass 2007) has been used to simulate the line-motions illusion in mammalian visual cortex and the spread of activity in rat barrel cortex upon whisker stimulation (Grimbert and Chavane 2007; Grimberty 2008). Wilson and Cowan (1972, 1973) and Amari (1977) type of neural fields have been used to model the VSD response of the visual cortex as well (Markounikau et al. 2010; Meyer 2007). Finally, the Jansen and Rit (1995) neural mass has been used in a description of VSD data concerning the connection between spontaneous and evoked activity in the visual cortex (Nguyen Trong et al. 2012).

Metabolic-Hemodynamic Signals: fMRI BOLD

EEG and MEG have excellent temporal resolution but modest to poor spatial resolution. At best one can localize activity with centimeter accuracy with these modalities. Furthermore, these electrophysiological signals are largely surface measures and are prone to error and bias for reconstructing subcortical brain activity. It should be mentioned though that the MEG at least can probably discriminate activity from the hippocampus, amygdala, and thalamus (Attal and Schwartz 2013). However, fMRI based on blood-oxygen-level-dependent (BOLD) contrast (Buxton 2009; Huettel et al. 2008; Logothetis 2008; Ramsey et al. 2002) can resolve activity essentially within the entire brain volume with millimeter accuracy. In combination with structural MRI providing a direct match to the underlying anatomical geometry, this has led to fMRI BOLD becoming immensely popular in cognitive neuroscience. While much initial research was directed toward functional specialization (“localizing

brain function”), more recently integration and connectivity have become the focus (Friston 2002; Mather et al. 2013; Poldrack 2012). Several methodological developments are of particular interest to NPMs: pattern-information fMRI (Formisano and Kriegeskorte 2012), which approaches the idea of neural population activity from the image analysis side; connectivity analysis based on fMRI (Biswal et al. 1995; McIntosh et al. 1996; Smith 2012), which parallels the efforts to integrate realistic brain connectivity mentioned above; and causal modelling of fMRI (Breakspear et al. 2010; Friston et al. 2003; Stephan et al. 2008; Stephan and Roebroeck 2012), which points the way forward for determining NPM state and parameters from data.

The basis of the fMRI BOLD signal remains incompletely understood. The “physical” aspect of the signal expression, which concerns exploiting differences in the magnetic susceptibility of oxyhemoglobin and deoxyhemoglobin, will not concern us here. The corresponding technology and signal analysis have been worked out sufficiently to leave the underlying physiology as the main challenge (Norris 2006). The key problems are the so-called neurovascular coupling, i.e., how neural activity influences the brain vasculature, as well as the ensuing hemodynamics, which ultimately creates the differences in deoxyhemoglobin concentration in tissue that the MRI records. We start with the hemodynamics and then come back to the question of neurovascular coupling later.

While the actual hemodynamics in the brain is highly complex (Handwerker et al. 2012), practically all studies using NPMs have opted for some variant of the simple “Ballon” (Buxton 2012) or “Balloon-Windkessel” description (Friston et al. 2000, 2003). The reason is primarily simplicity: to the NPM written in terms of ordinary or partial differential equations (ODEs or PDEs), this hemodynamic model adds only four further ODEs plus one observation equation. We provide here a version of the Balloon-Windkessel model for convenience.

The starred variables indicate the fixed point solutions of the ODE system for arbitrary neural

activity u^* . If one identifies this with the average resting state of the brain, compared to which either evoked activity or spontaneous activity fluctuations establish a BOLD contrast, then one needs to demand $y^* = 0$. It follows that $v^* = 1$ and $q^* = 1$; thus, $f^* = 1$ and finally $u^* = 0$. In other words, with this interpretation the neural activity u indicates the *deviation* from the resting state, not the absolute activity. The coupling parameter ε translates this activity into a vasodilatory impulse. In practice this parameter has to be adjusted to deliver an appropriate hemodynamic response given some model of neural activity u . As a rough guide one can use the following upper limit: if u is a sine wave with amplitude A , then setting $\varepsilon = \omega_0^2 \zeta / A$ will limit the change to the normalized flow f to less than 71%. We note that our form of Eq. 1 makes more transparent than the equivalent original one in Friston et al. (2000) that the vasodilatory signal is here modelled as a damped harmonic oscillator forced by the neural activity. The oscillator is significantly underdamped ($\zeta < 1/\sqrt{2}$) and has a resonant frequency $\omega_0 \sqrt{1 - \zeta^2} / (2\pi) = 0.088 \text{ Hz}$. This makes obvious that this hemodynamic response and hence ultimately the BOLD contrast will low-pass filter the neural activity, highlighting in particular changes at “glacial” frequencies of about 0.1 Hz.

The remaining question of the neurovascular coupling can now be stated like this: which function of one or more variables of the NPM should be used as a model of neural activity u ? There is unfortunately currently no clear answer to this question. To a considerable degree this is so because the experimental determination of the underlying physiological processes is far from finished (Hyder and Rothman 2012; Iadecola 2004; Lauritzen et al. 2012). Riera and co-workers assume that the excitatory and inhibitory synaptic activities contribute (roughly) equally by determining the concentration of nitrous oxide (Riera et al. 2005, 2006, 2007). Sotero and Trujillo-Barreto (2007, 2008) relate excitatory and inhibitory synaptic activity to total oxygen consumption as well as directly driving cerebral blood flow with excitation. Bojak

et al. (2010, 2011) only consider excitatory synaptic activity as driving glutamate uptake of astrocytes. More variety can be found in the current literature, but given the rather severe impact of the subsequent hemodynamics, it is possible that a lot of the details of the neurovascular coupling are not reflected in the final BOLD contrast. Here more work is needed to establish the right level of modelling for concrete applications. However, it is clear that the modelling of fMRI BOLD is possible with NPMs, both in temporal and spatial aspects; cf. Fig. 7.

The Balloon-Windkessel model is classically a “single-compartment model,” which ignores spatial embedding of the vascular anatomy and fails to ensure adherence to the basic laws of conservation (mass, momentum, charge, etc.). Recent work, marrying high-resolution fMRI acquisition with the treatment of the ensuing nonlinear mathematics, has addressed these limitations (Aquino et al. 2012, 2014); cf. Fig. 8. After deriving a closed set of PDEs from physiological principles, this work predicts that at sufficiently high spatial resolution, the hemodynamic signal in response to a spatially discrete visual stimulus unfolds as a travelling wave across the cortical surface for up to 5 mm. High-resolution fMRI of the visual cortex confirmed this prediction, yielding physiologically plausible parameter estimates for the PDEs (Fig. 9). While research into the spatial extent of the BOLD signal is in its early days, it is arguably an important development. In principle it should allow the disambiguation of the neuronal and hemodynamic contributions to the spatial properties of the BOLD signal. This is of particular relevance when inverting continuum NPMs or models that are defined on a highly resolved spatial mesh.

Multimodal Neuroimaging

The field of multimodal neuroimaging (Biessmann et al. 2011; Blinowska et al. 2009; Freeman et al. 2009; Mulert et al. 2008; Stufflebeam and Rosen 2007) is thus far dominated by statistical approaches. While the

methods being employed are often extremely complex and sophisticated, they share a similar objective, namely, to co-register the data from different modalities to the same location in the brain at the same time and then combine the evidence of activity there (Martinez-Montes et al. 2004). In consequence, if both modalities show high activity at a time in a location, then the statistically combined result will show a high result there; if both are low then the combination will be low; and if only one of them is high but the other low, the result depends on the details of the method and its assumptions but will be somehow intermediate. While this makes intuitive sense, it relies on the fundamental assumption that different neural states generate signals for the different modalities such that the resulting signals are distinct in every modality and covary in some relatively simple way across modalities. However, we have seen that the signal generation for neuroimaging is very involved, and a priori it is not clear that this assumption will hold true. For example, the EEG may be driven by the balance between inhibitory and excitatory synaptic activity, whereas fMRI BOLD may be driven dominantly by excitatory synaptic activity alone. In this case a neural state with both high excitation and high inhibition may show little signal in the EEG, as these contributions cancel, whereas it would lead to a large fMRI BOLD response. Or a large inhibitory input in the absence of excitation may exert a strong influence on the EEG, but not on fMRI BOLD. Only large excitation without corresponding inhibition would likely register a large signal in both modalities and be guaranteed to appear in the combined result above some threshold.

Clearly what is needed here is a proper generative model, and we have asserted that NPMs can provide it. This is in particular true for simultaneous recordings of multimodal data, since the same predicted neural state can be used in different ways to provide the initial stage of the different signal expressions for the various modalities. Currently, research has focused on combining EEG/MEG and fMRI predictions with NPMs. The focus of Kötter and colleagues, as recently

Neuroimaging, Neural Population Models for, Fig. 7 (a) A Liley neural mass (Liley et al. 2002) predicts the EEG alpha rhythm (time series as *blue* line, corresponding normalized power spectral density as *inset*) but also the fMRI BOLD response (*red* line) given additional “task signal” excitatory input (*green* line).

(Bojak I 2012, unpublished). The compression of many oscillations on the long timescale makes the EEG time series appear noisy. (b) A prediction of fMRI BOLD on the cortical surface rendered (c) into voxels, where only voxels above an activity threshold are shown. (Bojak et al. 2010, 2011)

Neuroimaging, Neural Population Models for, Fig. 8 Physiologically derived hemodynamic response function. (a) Local spatiotemporal input causes a change in arterial inflow of blood, setting up a pressure gradient ∇P . (b) This mass inflow deforms the surrounding tissue, exerting pressure on nearby vessels. (c) The rise in pressure causes further volume changes in adjacent vessels, which propagate outwards. Damping of the response occurs through blood viscosity and losses occur via outflow. (d)

The increase of local inflow increases oxygenated hemoglobin (oHb), reducing the amount of local deoxygenated hemoglobin (dHb). As oxygen is simultaneously passively extracted from blood, oHb is converted to dHb, causing a delayed rise of dHb during vessel relaxation. This change in the ratio of oHb to dHb drives the BOLD signal. (This is Fig. 1 of Aquino et al. (2012), reproduced under the Creative Commons Attribution License)

reviewed in Deco et al. (2011), was on investigating resting-state oscillations and the so-called default mode network (Raichle et al. 2001). A series of papers have established the ability to fit auditory task data (Babajani et al. 2005; Babajani and Soltanian-Zadeh 2006; Babajani-Feremi et al. 2008; Babajani-Feremi and Soltanian-Zadeh 2010). Riera and co-workers fit auditory and visual task data (Riera et al. 2005,

2006, 2007). Alpha rhythm blocking and correlation with BOLD have been studied as well (Sotero et al. 2007; Sotero and Trujillo-Barreto 2008; Valdes-Sosa et al. 2009). An investigation on how much information EEG and fMRI BOLD can contribute to a combined signal has been made by Deneux and Faugeras (2010). Bojak et al. (2010, 2011) studied the dependence of the predictions on the assumptions about brain

Neuroimaging, Neural Population Models for, Fig. 9 Spatiotemporal snapshots showing the fMRI BOLD response to a discrete visual stimulus. Colors represent percentage signal change as indicated by the color

bar. (This is part of Fig. 3 of Aquino et al. (2012), reproduced under the Creative Commons Attribution License)

connectivity, as shown in Fig. 10. A first complete and freely available software package for carrying out such investigations has become available (Ritter et al. 2013; Sanz Leon et al. 2013).

Bayesian Model Selection and Inversion

Thus far we have chiefly focused on the physical aspects of embedding NPMs into cortical geometry and the forward model that maps neuronal activity from their cortical sources into sensor space. These measurement functions are crucial as they allow one to use NPMs to predict a broad range of cognitive and pathological states, from resting-state conditions (Cabral et al. 2011; Deco and Jirsa 2012; Honey et al. 2007; Robinson et al. 2001) over anesthesia (Bojak and Liley 2005) to epilepsy (Breakspear et al. 2006), which can then be tested against empirical recordings. However, arguably an even more powerful role for detailed forward models is that they enable the estimation of the likelihood of a particular NPM given a particular data set. That is, when framed in an appropriate variational scheme – such as empirical Bayes – forward models allow one to estimate the relative posterior likelihood of one or more models. Using an appropriate term that penalizes models for their complexity, this approach then allows one to infer which model, among a family of competing models, is most likely (or has the highest exceedance likelihood). It is then possible to infer the parameter values of the winning model – or, alternatively, estimate

model parameters across families of models, where each model contributes to the average according to its own likelihood (Trujillo-Barreto et al. 2004).

Dynamic causal modelling (DCM) exemplifies this approach, initially adopting standard variational techniques (Friston et al. 2003) before more recently moving toward innovative approaches based on free energy (Friston et al. 2007). Early work combining DCM and NPMs used a version of the Jansen and Rit (1995) model to analyze EEG- and MEG-evoked responses (David et al. 2006; Kiebel et al. 2006). This was followed by a frequency-domain analysis of steady-state responses (Moran et al. 2009, 2011). Daunizeau et al. (2009) then extended these methods in order to take spatial activity spreading into account, including stochastic effects and biologically more realistic propagation later on (Daunizeau et al. 2012). Finally, with increasingly sophisticated forward models and variational schemes, multimodal fusion using symmetrical model inversion is also becoming increasingly feasible (Valdes-Sosa et al. 2011).

Summary

NPMs are a natural candidate for the prediction and analysis of neuroimaging data, in particular, of the noninvasive kind that can be recorded without ethical constraints from humans. By their mathematical construction, NPMs describe precisely those compact and collective actions of

Neuroimaging, Neural Population Models for, Fig. 10 A model of the cortex with over 17 thousand neural masses and over 30 million connections (Bojak et al. 2010, 2011). The *middle* column shows the LFP (mean excitatory soma membrane potential) prediction, the *left* column the volume-conducted prediction of scalp EEG potentials including the recordings from three

electrodes shown in *purple*, and the *right* column shows the simultaneous fMRI BOLD prediction. As the strength of connectivity between anterior visual cortex and frontal eye field is raised from (a) 60% over (b) 85% to (c) 90% of the strength of background connectivity, drastic changes in the brain dynamics occur which are particularly visible in the fMRI BOLD prediction

neurons that due to the practical measurement physics also dominate the signal recordings. Much progress has been made in the last three decades in clarifying and specifying the signal expression part of this prediction “pipeline.” In consequence, we can now match the underlying NPMs (and NPM-driven physiological models) to

the measured data with unprecedented accuracy. This should lead to a new phase of expansion and sophistication in the development of NPMs driven by experimental data. We believe that the current surge of interest in NPMs is just a beginning and that the marriage of neuroimaging and NPMs will have a long and fruitful scientific future.

Definition

Cytokines are immuno- and neuromodulatory proteins secreted by immune cells, endothelial cells, pericytes, neurons, and glia. Cytokines function through network interactions at the

intracellular, intercellular, and tissue levels of analysis. These proteins influence excitability in neurons and neuroinflammatory functions of glia. Glial cells including astrocytes and microglia are generally implicated in CNS homeostasis. These cells monitor the neurochemical milieu in the CNS through dynamic filopodia. Astrocytes and microglia regulate responses to injury, infection, neurodegeneration, and hyperexcitability through cytokine release. The relative proportions of cytokines in the CNS microenvironment are thought to coordinate a balance between homeostasis, neuroinflammation, and disease. Hence, many studies analyze and interpret data through a broad categorization of cytokines into pro- and anti-inflammatory groups. However, the complexity of intra- and intercellular cytokine signaling and regulatory interaction networks necessitates a new conceptual framework that explicitly considers the dynamics of multiscale interactions and regulatory influences between cytokines. A convergence of cell type-specific assays, unbiased/high-dimensional data analysis, and computational modeling is required to identify critical control points in these regulatory networks governing homeostasis and neuroinflammation.

Detailed Description

Cytokine Networks and Regulation

Cytokines are soluble peptides that are secreted by immune and many nonimmune cell types throughout the body. Their signature functions involve coordination of primary immune responses to injury and infection, resolution, repair, and remodeling. Cytokines influence chemoattraction and cell phenotype polarization through intracellular signaling and transcriptional regulation. In the CNS, cytokines have been shown to influence neuronal excitability, cellular energetics, and processes implicated in neurodegeneration, infection, and injury. Such processes include inflammatory signaling, phagocytosis, fibrosis, and the regulation of blood flow and blood brain barrier integrity. CNS cells both secrete and respond to extracellular cytokines through G-protein coupled receptor signaling.

A wealth of experimental data shows that cytokines influence the production and responses to other cytokines, in terms of both autocrine and paracrine signaling (Anderson et al. 2015; Benveniste 1992). Thus, there exists a cytokine regulatory interaction network within each cell type as well as across cells in a tissue (Fig. 1).

In the early 1990s, Benveniste and colleagues highlighted the concept of “cytokine networks” in the context of neuroscience (Benveniste 1992). Their work demonstrated that so-called pro-inflammatory cytokines such as tumor necrosis factor- α (TNF α) and interleukin 1- β (IL1 β) stimulated the upregulation of both “pro-” and “anti-inflammatory” cytokines including IL10 and transforming growth factor- β (TGF β). This work showed that cytokines respond to changes in the levels of other cytokines with distinct kinetic profiles, and the underlying interaction networks are densely coupled with both positive and negative feedbacks (Anderson et al. 2015). While the designation of cytokines as either pro- or anti-inflammatory has provided useful heuristics regarding the molecular basis of the immune response and immunosuppression, there are important shortcomings to the binary classification.

Cytokine perturbations have yielded pleiotropic effects and therapeutic outcomes that were unexpected according to existing pro/anti categorizations. For example, the canonical pro-inflammatory cytokine TNF α was shown to confer neuroprotection to brain injury and β -amyloid induced cell death, as well as reparative remyelination under conditions associated with multiple sclerosis (Sriram and O’Callaghan 2007). Administration of the anti-inflammatory cytokine IL-10 has shown inconsistent therapeutic effects for treating conditions associated with multiple sclerosis and deleterious effects for treating conditions associated with Alzheimer’s disease (Lobo-Silva et al. 2016). Importantly, human clinical trials have shown that interventions involving TNF α inhibition were associated with exacerbated symptoms for multiple sclerosis patients (Connor 2011). It has been proposed that the timing of a therapeutic intervention relative to disease progression is critical for treatment efficacy.

Collectively, our current knowledge is inconsistent with the prevailing paradigm in which cytokines are considered to be either “good” or “bad” for tissue function and organ/organism health. Available data are consistent with the notion that the function of an individual cytokine cannot be isolated from its role within a coupled regulatory network, the behaviors of which are constrained by network connectivity and interaction kinetics. Investigative approaches following the network view will require new multiplex time-series data and integrated modeling approaches (Anderson and Vadigepalli 2016). At the cellular level, it is necessary to improve our understanding of the kinetics and mechanisms of cytokine interactions, which involve multifaceted molecular functions including transcriptional regulation, biochemical signaling, and receptor regulation/trafficking (Cilfone et al. 2013; Rodriguez-Fernandez et al. 2013).

Glia and Cellular Microenvironment

While most CNS cell types have been documented as capable of cytokine production, microglia and astrocytes are currently considered to be the primary contributors to cytokine regulation in the CNS. Microglia are self-renewing resident macrophages of the CNS that are derived from the hematopoietic system early in embryological development. Astrocytes have a distinct developmental origin in the neuroectoderm, as do neurons (Reemst et al. 2016). In a healthy state, microglia and astrocytes survey the neurochemical milieu in the CNS parenchyma, provide energy substrates to neurons, and influence synaptic transmission through “quad-partite” synapses (Schafer et al. 2013). Under pathological conditions, glial cells migrate to sites of injury or degeneration where they perform a number of context specific functions. In addition to cytokine secretion and regulation of neurochemistry, glial cells exert mechanical influences that are manifested in morphological changes (Anderson et al. 2017a). Studies at the single cell level have been informative in regard to how glial cells collaborate to regulate homeostasis in aging and pathogenic responses (Hammond et al. 2019; Masuda et al. 2019).

Glial cells, microglia in particular, are believed to exhibit pro- or anti-inflammatory phenotypes, where phenotype polarization is controlled by extracellular cytokines. However, it has been argued that immune cells exhibit a range of phenotypic states that fall outside of the pro/anti axis (Perry et al. 2007). Furthermore, small subsets of cells within a population could exert a disproportionate influence on the neurochemical microenvironment. For example, less than 5% of macrophages in a cell population can account for ~60% of the cytokine released from the cell population following an inflammatory stimulus (Xue et al. 2015). Single cell omics assays are beginning to unravel the true complexity in the distribution of functional phenotypes of glia and neurons. Such atlases of molecularly defined CNS cell phenotypes need to be analyzed in the context of interactions between microglia, astrocytes, neurons, and other cells, to further our understanding of neuroinflammation.

Neuroinflammation

A critical aspect of many neuroinflammatory conditions is the infiltration of peripheral immune cells and the diffusion of peripheral cytokines into the CNS. Under inflammatory conditions associated with neurodegeneration or traumatic injury, monocytes and lymphocytes enter the CNS and contribute to inflammatory regulation therein. Understanding the functional contributions of peripheral immune cells to pathological responses is complicated (Greenhalgh et al. 2018). It is also widely accepted that peripheral tissues release substances into circulation that can influence the CNS. The liver releases “hepatokines” (hepatic cytokines), muscles secrete myokines, and adipose tissues secrete adipokines into circulation. Therefore, circulating cytokines from multiple sources can access the CNS. The inevitable conclusion is that CNS inflammation is coupled to the organismal physiological state, the study of which necessitates a network of networks approach to probe the multiorgan interaction dynamics (Anderson et al. 2017b; Fig. 1).

The conventional characterization of neuroinflammation as a good versus bad phenomenon, based on the predominant expression of pro- versus anti-inflammatory cytokines and

Neuroinflammation, Glia, and Cytokines: Networks of Networks, Fig. 1 Networks of networks underlying CNS regulation. Physiological homeostasis depends on multi-organ communication (gray box). Multi-cellular

interactions involve cytokine signaling in the CNS (red box). Cytokine regulation involves cytokine networks (blue box). Intracellular signaling pathways mediate cytokine interactions (green box)

changes in cell morphology/function, is an oversimplification. Studies of cytokine expression have shown that protein levels often show less variation between healthy and inflammatory conditions as compared to transcript levels (Perry et al. 2007). Various combinations of cytokine balances are observed under distinct inflammatory conditions, clearly pointing to a multidimensional cytokine state space that needs to be considered, rather than a conventional linear axis spanning good and bad neuroinflammatory states. Moreover, inflammatory signaling is present during development when synaptic pruning occurs and inflammatory signaling is implicated in

learning/memory (Wu et al. 2015). In general, inflammation has evolved as a means to maintain homeostasis in the organism. The functional outcome of inflammation critically depends on the combination of inflammatory markers expressed and the duration of signaling activity. A central difficulty in understanding neuroinflammation is mapping molecular and cellular functions to physiological, metabolic, and functional states of the CNS tissue. This task is difficult given that molecular interaction networks are embedded in multicellular interaction networks, and the signal processing proceeds dynamically following an inflammatory trigger. It is

often not possible to distinguish causes from consequences of network output. While blocking specific network elements may provide limited insight into therapeutic approaches, the ablation approach provides limited insight into the functional role of the corresponding element in the context of the embedded network. Mathematical and computational approaches, including modeling, are needed to address these issues.

Computational Modeling of Cytokine Networks, Glia, and Neuroinflammation

Mathematical and computational approaches are integral to understanding complex systems. The high-dimensional state space underlying neuroinflammation generally precludes the application of formal mathematics, necessitating the use of computation. Computational approaches typically include either machine learning or modeling. Both machine learning and modeling approaches have a vast spectrum of conceptual and technical paradigms. While machine learning is well suited to define groups of related cytokines (unsupervised) or define groups of cytokines/cell states that are associated with particular phenotypic states (supervised), these approaches typically offer limited insight as to how biological properties relate to observed data in terms of “mechanisms.” Machine learning approaches are particularly well suited for inferring network structures and identifying potentially important network elements. Modeling approaches are generally much more concerned with providing an explanation for system behavior in terms of biological functions. The networks of networks underlying neuroinflammation can be conceived as a layered set of functions across scales: neuroinflammation state = f (distribution of cell states across cell types, cell-cell interactions, microenvironment), cell state = f (relative cytokine levels), cytokine levels = f (cell signaling, molecular interaction networks), where all variables are time-dependent (Fig. 1). For instance, cytokine networks consist of interactions between discrete cytokines at a course-grained level of analysis. Each interaction edge results from multiple signaling proteins, which are often arranged in complex motifs involving feedback regulation.

In turn, each signaling event (e.g., receptor-ligand binding, protein phosphorylation) is the result of structural protein modifications that can be considered as a network of conformational states. Machine learning applications are generally agnostic to the functional forms (e.g., linear versus sigmoidal), whereas these functional forms are integral to model development and interpretation. However, the idea has been advanced that better understanding the underlying functional forms of a particular problem can improve the performance of optimization algorithms (Wolpert and Macready 1997). It is sometimes the case that model complexity precludes the generation of understanding without the aid of machine learning approaches, in which case machine learning paradigms can be integrated with modeling to enhance progress (Anderson et al. 2016). Modeling approaches in the context of neuroinflammation and elsewhere have yielded important insights that are difficult if not impossible to derive from alternative approaches.

Both machine learning and dynamic models have been leveraged to study CNS disease, as reviewed previously (Anderson and Vadigepalli 2016). For example, a Boolean logic-based model addressed how/why microglia fail to phagocytose β -amyloid in aging and Alzheimer's disease (Anastasio 2015). A key to the utility of computational approaches to neuroinflammation is the formulation of important questions that can help explain unexpected findings or reveal system properties. Agent-based models are also well suited for studying neuroinflammation, as demonstrated through studies of peripheral immune function, because the computational framework supports multiscale representations of intracellular cytokine signaling and cell to cell interactions (Cilfone et al. 2013). Thus, agent-based models can simulate intracellular and multicellular networks in tandem. Studies of populations of networks representing a spectrum of individual differences are also becoming popular modeling approaches with potential implications for precision medicine.

Dynamic ordinary differential equation models are particularly useful for gaining an understanding of how systems work and what

sorts of tradeoffs govern their behaviors. For instance, our analyses of microglial cytokine networks revealed counterintuitive influences of IL10 on TNF α that were related to both network topology and the relative kinetics of multiple cytokines (Anderson et al. 2015). To understand system functions and determine an optimal therapeutic intervention strategy, it is useful to distinguish between the extent to which a given variable contributes system behavior and effect of removing the variable from the system (contribution versus sensitivity). Model analyses have revealed cases in which the removal of variables with large contributions to physiological processes shows relatively small consequences for system behavior (large contribution, small sensitivity). In contrast, removal of a variable with a relatively small functional contribution in the intact system can lead to comparatively drastic influences on function (small contribution, large sensitivity). Such a scenario can occur when redundant functional mechanisms are available to compensate for the absence of a variable that is typically associated with a prominent influence on system behavior, as revealed by model analysis (Pradhan et al. 2016).

Regardless of the problem's scale, the integration of multiple experimental and computational approaches helps to generate deeper insights. Studies that combine statistical approaches to experimental data analysis with dynamic modeling have been applied successfully to generate novel understanding of system behavior under the general paradigm of control theory (Cowan et al. 2014; Davis 2006). Doyle and colleagues approached the problem of understanding cardiovascular control by classifying relevant physiological variables as either homeostatically controlled variables, control actuators, disturbance variables, and network feedback variables. In the context of physiology, actuators are control elements that generate physical or chemical movement (e.g., the motor neuron controls muscle fiber contraction), while disturbance variables can represent changes in the demands imposed on the system (e.g., elevated workload imposed on the muscle). Key insights of general importance were that actuator variability is responsible for maintaining homeostasis in the face of fluctuating disturbances, and actuator saturation can balance

tradeoffs between system efficiency and the homeostasis of controlled variables (Li et al. 2014). In a conceptually similar approach, Ogunnaike used a process control-based approach to describe a system characterized by a digital-to-analog signal conversions between single cell behaviors and the cell population responses (Ogunnaike 2006). Such control theory-based paradigms provide important examples of integrated approaches that could enhance our understanding of neuroinflammation.

Approaches from fields throughout neurosciences and elsewhere provide critical tools for integrated studies of neuroinflammation in which modeling is used to gain insights and generate predictions. An important avenue for future research would be to integrate computational models of intra- and inter-cellular cytokine networks with multiscale models of cell signaling influences on ion channel function and excitability (Makadia et al. 2015). Moreover, considering neuroinflammation in the broader context of multiorgan networks will enhance our understanding of CNS diseases and their potential treatments (Anderson et al. 2017b). In conclusion, the mechanistic and functional relationships connecting cytokines, glia, and neuroinflammation represent networks within networks of signaling and functional mechanisms interacting across multiple spatial and temporal scales.

Neuromechanics of Balance

► Neuromechanics of Postural Control

Neuromechanics of Joint Coordination

Young-Hui Chang

School of Applied Physiology, Georgia Institute of Technology, Comparative Neuromechanics Laboratory, Atlanta, GA, USA

Definition

“Neuromechanics of joint coordination in locomotion” addresses the control of synchronized

dynamics across multiple limb segments during legged locomotion. It requires integrating perspectives, principles, and methods across the disciplines of neuroscience and biomechanics. The neurophysiological basis for locomotion is tuned to the intrinsic biomechanical constraints and conditions presented by both the organism's biology and the implicit mechanical tasks required of legged locomotion. It is, therefore, necessary to study joint coordination within the context of identifiable performance goals, which are defined by the biomechanics of the task. Joint coordination can be then viewed as the changes that occur at one joint in response to deviations at another joint with the superseding goal to support a task-level locomotor performance goal.

Detailed Description

Redundancy Is Intrinsic to Legged Locomotion

Legged locomotion requires the coordinated output of numerous neuromechanical elements. Within a single limb these elements can include thousands of motor units across several muscles that cross multiple joints, creating motor redundancies at each level of organization. For example, in the human leg, there are an infinite number of ankle, knee, and hip joint angle combinations that can satisfy any one single end-point (toe) position. These angular positions are a result of muscle-tendon unit lengths influenced by the nervous system to act across the joints. How the nervous system selects from among the many possible joint angle combinations to maintain a consistent end-point position during a task is considered a fundamental problem in motor control (Bernstein 1967). This problem of motor redundancy has been traditionally studied in the control of upper extremity movements but can be similarly applied to the control of the legs during locomotion where the position of the toe relative to the body changes through a characteristic pattern over time.

It is not well understood how the joints of the leg are coordinated during locomotion. One possibility is that the nervous system controls each

joint independently during locomotion. For example, the nervous system could potentially assign values for each joint angle at each instant in time throughout the gait cycle independent of other joints. But, this would require many high-level computations to ensure that a performance goal, such as toe position, be met during stepping. Alternatively, to reduce bandwidth at the highest levels of the neural controller, the coordination that occurs across joints may be relegated to lower levels of the nervous system where the compensatory actions across joints are made through relatively automatic regulatory processes such as through spinally mediated pathways or even passive mechanics. This latter solution would allow higher levels of the controller to directly set and modify performance level goals, such as toe position, that may be governing the joint coordination regulated at lower levels. There is mounting evidence for this latter solution, which would suggest that the locomotor control system is hierarchically organized (Loeb et al. 1999). If an automatic regulatory process can coordinate the joints for the purpose of satisfying this performance goal, then joint-level redundancy could actually lead to more consistent locomotor performance as it allows for immediate access to alternative solutions in the face of natural variation and perturbation (Schöner and Kelso 1988; Latash et al. 2002).

Locomotor Performance Goals Provide Context for Joint Coordination

Viewing the seemingly complex actions of the joints within the context of limb performance goals provides a framework within which to synthesize control principles for joint coordination. The identification of these locomotor performance goals, however, remains an active area of research. The biomechanical constraints of locomotion are important to consider in this regard because they bound the space within which the nervous system is likely to act. They provide important clues as to how the control of these complex joint movements is organized. Notably, independent findings from biomechanics and neurophysiology have proposed similar ideas about how the locomotor system may organize the

neuromechanical control of the joints during legged locomotion. Both control schemes suggest a considerable hierarchical reduction in the number of parameters that are attended to at higher levels of the nervous system.

Using evolution as a natural experiment to uncover locomotor performance goals across species, a wide range of morphologies and taxonomic groups are observed to exhibit very similar center of mass dynamics (Cavagna et al. 1977; Dickinson et al. 2000; Full and Koditschek 1999). Two major biomechanical templates for describing the center of mass dynamics of legged locomotion are the inverted pendulum model of walking and the spring-mass model of running (Fig. 1). For example, birds, mammals, and arthropods all exhibit the same spring-mass dynamics of the center of mass during running, often referred to as a bouncing gait (Dickinson

et al. 2000). The fact that a 2-legged bird, a 4-legged horse, and a 6-legged cockroach all move their bodies in the same way suggests that the biomechanical performance goals for running are fundamental to legged locomotion and are low dimensional in nature. Furthermore, the highly variable morphological “details” of the limbs (i.e., the number of joints and muscles, type of skeleton) appear inconsequential to body dynamics. The nervous systems across all of these different groups of animals coordinate the elements of their respective neuromechanical systems to satisfy these simple biomechanical templates for body center of mass dynamics.

The center of mass dynamics is controlled in large part by the net actions of the legs. Therefore, it is important to understand limb function and its role in governing joint coordination to achieve

Neuromechanics of Joint Coordination, Fig. 1 Walking involves a cyclical rise and fall of the body’s center of mass with each step, where the body is at its highest point in the middle of the stance phase (a). The center of mass dynamics of walking in a number of legged animals has been successfully idealized with an inverted pendulum model characterizing the stance phase of walking as a point mass upon a massless, rigid strut (b).

Running, trotting, and other bouncing gaits involve a similar rise and fall of the body’s center of mass to walking; however, the body is now at its lowest point in the middle of stance phase (c). Bouncing gaits across a wide range of animals have been successfully idealized as a point mass sitting atop a massless linear spring or mass-spring model (d)

consistent center of mass dynamics. The inverted pendulum and spring-mass models each implicate overall hip-to-toe length, orientation, and end-point force as important parameters that are likely controlled during locomotion (Dickinson et al. 2000). For example, humans maintain a highly consistent relationship between limb force and limb length (typically referred to as a “leg stiffness”) in running and hopping gaits. This spring-mass model that describes running and hopping is robust against changes in ground viscoelasticity (Ferris et al. 1998; Moritz and Farley 2003) and application of mechanical loads to individual joints (Ferris et al. 2006; Chang et al. 2008). The biomechanics of locomotion, therefore, limits the set of likely locomotor performance goals, which can be tested as hypothetical neural control targets.

Neurophysiological studies also suggest that the sensorimotor control of locomotion is simplified through a hierarchical reduction in the number of control parameters represented at the highest levels of control. These parameters reflect the same limb performance goals independently suggested from biomechanics. For example, dorsal spinocerebellar tract neurons within the cat spinal cord are observed to integrate a large amount of sensory information from the periphery into relatively simple neural representations that ascend into the cerebellum (Bosco et al. 1996, 2000, 2003, 2006; Bosco and Poppele 2000, 2003; Poppele et al. 2002). These studies of sensory encoding suggest that general limb kinematics (hip-to-toe length and orientation) and kinetics (end-point force) are monitored by the central nervous system. Motor systems also indicate that relatively simple, low-dimensional control signals from synergistic muscle activations represent task-level commands. Thus, a handful of muscle synergies can account for the complex, high-dimensional motor output observed during locomotion (Chvatal and Ting 2012, 2013; Chvatal et al. 2011; Ivanenko et al. 2004). These studies indicate that sensorimotor control of the muscles is intrinsic to the patterns of joint coordination during locomotion, which naturally emerge as a result and can be used as a window into the control schema of the nervous system.

Uncontrolled Manifold Framework for Testing Task Space Utilization

Looking at joint coordination in the context of whole limb function provides a way to reduce dimensionality of the system in a comprehensible manner in which the nervous system may itself be operating. The uncontrolled manifold (UCM) concept introduces a computational approach to mathematically transform cycle-by-cycle variability of joint dynamics from an anatomically defined coordinate system into one derived by their effect on a hypothesized control parameter (Scholz and Schöner 1999; Latash et al. 2002). Over many repetitive gait cycles, one can use the UCM approach to quantify the variance structure of the joint dynamics within this goal-defined task space. For example, a nonrandom distribution of joint angle variance that distributes and aligns with a subspace of equivalent solutions for limb length indicates a strong likelihood that the nervous system is selectively minimizing only those joint angle deviations that lead to inconsistent limb lengths. In contrast, joint angle deviations within this subspace result in consistent limb kinematics and are left “uncontrolled” within this manifold. This type of control is characterized by a minimal intervention strategy where the deviations in joint dynamics that do not negatively affect performance are allowed to accumulate in this task equivalent space (Todorov and Jordan 2002).

For example, if we were to investigate the variance structure of a set of three joint angles relative to their influence over a performance goal such as leg length, we could estimate the 2-dimensional manifold as the null space ($\vec{\epsilon}$) of a Jacobian (J) that relates small changes in the joint angles to small changes in leg length relative to a reference posture ($\vec{\Theta}^0$, Eq. 1).

$$0 = J \left(\vec{\Theta}^0 \right) \cdot \vec{\epsilon} \quad (1)$$

We analyze the data at specific time slices within the gait cycle over many successive cycles. We define our reference leg posture ($\vec{\Theta}^0$) as the average set of joint angles measured at that

specific time in the gait cycle over all trials. Projecting the deviations of joint angles ($\vec{\Theta}$) from this reference posture onto the null space ($\vec{\varepsilon}_i$) determines the fraction of deviations that did not affect the performance goal, which we will call goal equivalent deviations ($\vec{X}_{GED}$, Eq. 2). Others have referred to these as task-irrelevant deviations since they do not alter the hypothesized performance goal (see Todorov and Jordan 2002). The remaining fraction is then deemed to be orthogonal to the null space, which we refer to as non-goal equivalent deviations ($\vec{X}_{NGED}$, Eq. 3) or task-relevant deviations.

$$\vec{X}_{GED} = \sum_{i=1}^n \vec{\varepsilon}_i^T \cdot \left(\vec{\Theta} - \vec{\Theta}^0 \right) \cdot \vec{\varepsilon}_i \quad (2)$$

$$\vec{X}_{NGED} = \left(\vec{\Theta} - \vec{\Theta}^0 \right) - \vec{X}_{GED} \quad (3)$$

The amount of variance normalized per degree of freedom (n) parallel to the UCM is then defined as goal equivalent variance (σ_{GEV}^2 ; Eq. 4).

$$\sigma_{GEV}^2 = \frac{\sum \vec{X}_{GED}^2}{nN_{cycles}} \quad (4)$$

And, the amount of the variance per degree of freedom (d) orthogonal to the UCM is defined as non-goal equivalent variance (σ_{NGEV}^2 ; Eq. 5).

$$\sigma_{NGEV}^2 = \frac{\sum \vec{X}_{NGED}^2}{d \cdot N_{cycles}} \quad (5)$$

To quantify the variance structure over all locomotor cycles, we can compare the relative amounts of σ_{GEV}^2 and σ_{NGEV}^2 through a normalized difference calculation, which we term the index of motor abundance (IMA, Eq. 6). An IMA value greater than zero indicates that the joint angle deviations having a direct effect on deviations in leg length were preferentially minimized, indicating leg length to be a likely performance goal for locomotion. An IMA equal to zero indicates no preference for minimizing deviations of leg length since all joint angle deviations were randomly distributed in the task space.

$$IMA = \frac{(\sigma_{GEV}^2 - \sigma_{NGEV}^2)}{(\sigma_{GEV}^2 + \sigma_{NGEV}^2)} \quad (6)$$

This general approach has been used to test the hypothesized control parameters: limb length, limb orientation, and limb force during human hopping. Human hopping is a commonly used experimental paradigm for locomotion that provides spring-mass dynamics of the center of mass, while giving a highly controlled experimental design to study the coordinated actions of the joints. Recent studies have shown that, indeed, subjects selectively minimize joint kinematic deviations in the task-relevant dimension to result in more consistent values of limb length and limb orientation (Auyang and Chang 2013; Auyang et al. 2009; Fig. 2).

Furthermore, humans also minimize joint torque deviations in the task-relevant dimension to stabilize peak limb force during hopping (Yen et al. 2009; Yen and Chang 2010). The practical result is that despite generating large and highly

Neuromechanics of Joint Coordination, Fig. 2 During hopping and running, the length and orientation of the hip-to-toe limb kinematic vector are stabilized by the coordinated actions of the joints. Limb length (a) and limb orientation (b) are made more consistent from cycle to cycle through joint actions as evidenced by the nonrandomized variance structure of the joint kinematics when viewed in the task space relative to each of these parameters (i.e., a positive IMA value). Limb length is stabilized during the stance phase (a), whereas limb orientation is typically stabilized during the aerial phase (b). (Adapted from Auyang and Chang 2013)

Neuromechanics of Joint Coordination, Fig. 3 The variance of joint torques is at its peak during the middle of stance phase of hopping and running (a). Yet, the force variance at this same instant is experiencing a local minimum (b). This indicates that the peak forces generated on the ground are highly consistent even when joint torques are at their greatest magnitudes and most variable

variable joint torques from one hop to the next, the variability of the peak limb force generated against the ground is minimized (Fig. 3).

A closer look at joint torque coordination effects on force stabilization is permitted with a data permutation technique that allows isolation of the variance structure due only to joint torque covariance (Yen and Chang 2010). This analysis reveals that the effectiveness of joint torque coordination to produce more consistent force is rate dependent, and a trade-off exists at higher hopping frequencies where individual control of the ankle joint torque is the dominant strategy for stabilizing force. Study of human walking within the framework of the UCM concept has revealed similar control strategies for stabilizing force in a hierarchical manner (Toney and Chang 2013).

Neural Mechanisms for Joint Coordination During Locomotion

It is not clear what substrates within the mammalian nervous system form the neural

representations of locomotor performance goals; however, evidence for such a control strategy is increasing. In two species, hip-to-toe limb kinematics are preferentially preserved through coordinated changes in the joint kinematics after neuromuscular injury. In awake behaving cats (Chang et al. 2009) and rats (Bauman and Chang 2013), paralysis in the ankle extensor muscles through peripheral nerve damage leads to large joint angle deficits at the ankle during locomotion. Significant, associated changes also occur in the hip, knee, and toe joint kinematics. The net result of all of these changes to the joint kinematics, however, resulted in no change in the hip-to-toe limb length and limb orientation trajectories (see Rat Video, <http://youtu.be/XsM3f0UYG5w>). This preservation of limb kinematics after neuromuscular injury occurred despite fundamentally different interjoint coordination patterns adopted across the joints (Bauman and Chang 2013). Importantly, the same muscle nerve injury paradigm does not elicit immediate preservation of limb kinematics in a walking decerebrate cat preparation where the cerebral cortices have been removed (Stahl and Nichols 2011). This indicates that the maintenance of limb kinematics after injury requires cortical input. Increases in cortical activity during cat locomotion are associated with walking in complex environments and specifically implicated for making modifications during locomotion (Beloozerova and Sirota 1993a, b, 1998; Drew et al. 2008). Subpopulations of motor cortical neurons are suggested to modify the magnitude and phase of muscle synergies that control limb trajectory (Drew et al. 2008). This finding supports earlier suggestions that reduced dimensionality and covariance of joint kinematics in human locomotion is not due to biomechanical coupling, but involves a control process including the neural representation of limb kinematics (Ivanenko et al. 2008). The persistence of limb kinematics through large-scale, coordinated adaptation of joint kinematics after injury appears to require involvement from higher brain centers.

Rapid spinal mechanisms are in place, however, that may explain the more subtle coordinative changes that occur on a regular basis during normal, steady-state locomotion. Heterogenic

proprioceptive feedback from the muscles of the leg is seen to help stabilize end-point position in the cat hindlimb (Bunderson et al. 2007). Spinal pathways in the cat that send force and length feedback between ankle extensor muscles and knee extensor muscles can account for these automatic adjustments across the joints. A strong excitatory coupling exists from the vastus muscles crossing the knee to the soleus muscle crossing the ankle (Wilmink and Nichols 2003). For example, an induced knee flexion would stretch the vastus muscles crossing the knee joint and cause excitation of the soleus muscle. The resulting ankle extension would tend to compensate for the induced knee flexion to preserve hip-to-toe leg length. Additionally, there is a strong bidirectional force-dependent inhibition between the triceps surae group and the quadriceps group (Wilmink and Nichols 2003). Thus, an induced increase in knee torque would generate a decrease in ankle torque and vice versa, resulting in a tendency to maintain end-point force. Although the effect of these spinal pathways has not been tested with regard to locomotor performance goals, they provide a testable hypothesis for regulatory pathways at lower levels of the nervous system with which automatic coordinated adjustments may take place across the joints on a stride-by-stride basis. These spinal pathways also provide the framework within which greater magnitude chronic adaptations can be made over longer periods of time with involvement of the higher brain centers, such as is required after a neuromuscular injury.

Synonyms

[Neuromechanics of balance](#); [Sensorimotor control of balance](#); [Sensorimotor control of posture](#)

Definition

Although *postural control* often refers to the restoration of a particular body configuration defined by joint angles, in the context of standing balance control, it more generally refers to the strategies used to maintain the body's orientation and equilibrium in an unstable gravitational field, which may require a change in body configuration. *Neuromechanics* refers to the complex interactions between the nervous system and the musculoskeletal system in producing movements. These interactions result from the fact that the nervous system generates signals that activate muscles, but the forces and movements generated depend upon the state (e.g., displacement and velocity of muscles, tendons, and joints) as well as mechanical loads and forces associated with the musculoskeletal system and the environment. In turn, these neural signals to muscles are modified by the central nervous system in

part based on sensory signals generated by forces and movements of the body.

Detailed Description

Although the act of standing up seems like a simple motor task, our ability to balance while doing so is the result of complex neuromechanical interactions. There are many levels of contributions from both the nervous system and musculoskeletal system in producing posture and movement, which may be both complementary and redundant. Moreover, the neuromechanical interactions can change with any number of factors, including movement context, body configuration, the availability of sensory information, impairments to sensorimotor processing, and the ability of muscles to produce force. Understanding the multiplicity of solutions for maintaining postural control during standing is important for understanding how we move and how this ability is impaired across a range of neurological and musculoskeletal deficits, including Parkinson's disease, stroke, sensory loss, muscle atrophy, and limb loss, as well as normal changes with aging. Computational analyses and modeling techniques play a key role in dissociating the contributions of musculoskeletal dynamics versus sensorimotor processing to standing balance control when combined with experimental results.

Neuromechanics of Quiet Standing

Even in the absence of external perturbations, the body is in constant motion, referred to as postural or body sway. It has been debated whether this postural sway is due to feedforward neural mechanisms that cause the body to oscillate in the absence of any sensory input or from feedback motor signals in response to fluctuations in sensory signals that may be due to both movement and sensory noise. Although intrinsic muscle and tendon stiffness have been proposed to stabilize quiet standing, torque-actuated inverted pendulum models demonstrate that the necessary ankle stiffness is much higher than that measured experimentally

(Morasso and Schieppati 1999; Peterka 2002). Fluctuations in center of pressure (CoP) displacement have been reproduced by postural control models incorporating both feedforward and feedback neural control mechanisms. For example, a single inverted pendulum model controlled using delayed position and velocity feedback with simulated sensory noise can reproduce a wide variety of common time and frequency domain CoP measures (Maurer and Peterka 2005; Peterka 2002). In contrast, sway-like motion has also been demonstrated using a predictive feedforward mechanism (Gawthrop et al. 2009; Loram et al. 2005). Resolving this debate is challenging given limitations in system identification techniques in conditions where sensory noise is greater than external perturbations such as in quiet standing (van der Kooij et al. 2005).

Neuromechanics of Multisensory Integration During Postural Control

The flexible integration of sensory signals from the proprioceptive, vestibular, and visual systems is necessary for accurate estimation of body orientation with respect to vertical during perturbations to standing balance control. The variations in reliance on visual, vestibular, and visual information for feedback control of postural orientation have been demonstrated using a simple inverted pendulum model of the body controlled with a delayed feedback signal in which the reliance of different sensory signals could be changed (Peterka 2002). The model was used to reproduce experiments that produce sensory conflict by perturbing only the visual system (rotating a visual surround) or only the proprioceptive and vestibular systems (rotating the support surface with eyes closed). The reliance on proprioceptive information causes subjects to align their body with the tilting of the support surface, which occurs only for small support-surface rotation amplitude and frequencies. However, at larger amplitudes, subjects must increase their reliance on vestibular information to align themselves with the vertical when they can no longer stabilize themselves when orienting to the tilting of the

surface (Peterka 2002). Further, the model can predict the inability of individuals with vestibular loss to maintain stability at larger amplitudes with eyes closed because the proprioceptive strategy fails.

Neuromechanical Interactions During Balance Control

Variations in sensorimotor feedback with changes in body mechanics are also necessary to maintain balance in response to perturbations. This can be demonstrated by examining frontal-plane balance control in response to lateral perturbations where the distance between the feet changes the mechanics of the body. The necessary covariations in neural and mechanical contributions to postural stability can be demonstrated using a simple computational or robotic model of the body as two rigid legs connected by a pelvis with variable distance between the feet. In response to lateral motion of the support surface, a delayed feedback signal based on hip angle position and velocity drives the torque about that joint. As stance width is altered, the same sensorimotor feedback gain values can no longer be used to stabilize the system. Further, similar effects on postural stability in response to a lateral perturbation can be generated by changing either neural feedback gains or stance width, demonstrating neuromechanical redundancy in postural control. Indeed, large differences in the sensorimotor response to sensory signals are necessary to produce the same center of mass (CoM) motion when standing at wide versus narrow stance widths. However, within a given stance width, there is some allowable variability in the magnitudes of feedback gains that can be used to maintain balance that is corroborated by variations in neural feedback gains observed across individuals (Bingham et al. 2011).

Neuromechanics of Multisegmental Movement Strategies for Balance

Multisegmental biomechanical models reveal that biomechanical as well as neural influences govern the choice of multi-joint movement strategy in

balance control. Different multi-joint coordination strategies can be used to achieve the same higher task-level outcome due to redundancy in joint space. Typically, small perturbations to standing balance elicit motions predominantly about the ankle (“ankle” strategy), whereas larger perturbations that tend to place the CoM near the edge of the base of support evoke flexion or extension at the hips (“hip” strategy). While biomechanical models demonstrate the insufficiency of the ankle strategy for keeping the feet on the ground for larger perturbations (Kuo and Zajac 1993), there likely exist other reasons such as head or trunk stability that lead to the preferred selection of the ankle strategy for small perturbations. Models incorporating sensory dynamics and state estimation further demonstrate that selection of movement strategies may also depend on the ability of the nervous system to obtain reliable sensory information (Kuo 2005; van der Kooij et al. 1999).

Neuromechanics of Muscle Activity During Balance Control

Using neuromechanical models to reproduce muscle activity in response to perturbations has provided evidence that sensory estimates of body position drive the spatiotemporal patterns of muscle activity during perturbation to balance. In contrast to joint-based information, CoM kinematics reflect the task-level goal of maintaining the CoM over the base of support in balance control (Safavynia and Ting 2013a). Using a simple inverted pendulum model consisting of a delayed feedback on CoM acceleration, velocity, and displacement, the magnitude and timing of muscle activity can be reproduced in response to postural perturbations (Lockhart and Ting 2007; Welch and Ting 2008). Note that this model assumes that the CoM is accurately estimated by multisensory integration mechanisms (Peterka 2002). The model demonstrates that a “predictive” burst of muscle activity due to acceleration of the CoM at the onset of the perturbation allows a muscle to reach maximal activation prior to the peak displacement of the CoM; previously this burst was attributed to the triggering of a fixed neuromotor programs in response to perturbations. The neural

signals reflecting errors in CoM kinematics with respect to the desired position may also recruit motor modules or muscle synergies (Ting and McKay 2007) for balance control (Safavynia and Ting 2013b). Motor modules coordinate muscles across multiple joints and can produce consistent biomechanical outputs necessary across various postural strategies control (Chvatal et al. 2011; Ting and Macpherson 2005; Torres-Oviedo and Ting 2007).

While more complex musculoskeletal models have been useful in studying movement, none have yet been developed for postural control that have been rigorously validated across experimental conditions compared to the models described above.

Definition

NeuroML (Cannon et al. 2014; Crook et al. 2007; Gleeson et al. 2010; Goddard et al. 2001) is an international, collaborative initiative to develop a declarative computational language for describing detailed models of neurons, neuronal networks, and neural systems.

Detailed Description

Computational modeling is an important tool in the study of the complexity of neural dynamics.

However, existing simulation environments, tools for neuroanatomical analysis, and data analysis tools use a variety of data formats, making it difficult to exchange models or reproduce computational studies. The NeuroML project was initiated to address these issues (Goddard et al. 2001). As outlined on the website at <https://www.neuroml.org/>, the main aims of the NeuroML initiative are:

1. To create the specifications that define an XML language for describing the biophysical properties, anatomy, and network architecture of neuronal systems at multiple spatial scales
2. To provide greater transparency and accessibility of models, facilitating the exchange of models among researchers
3. To aid the development and promotion of software tools and databases that support NeuroML to facilitate model sharing
4. To encourage researchers who create models within the scope of the initiative to exchange and publish their models in the NeuroML format

History

The term “NeuroML” was first introduced by Goddard et al. (2001) following meetings in Edinburgh at which initial templates for the language structures were discussed. The proposal was built on general-purpose structures already proposed by Gardner et al. (2001). Initially, NeuroML development was centered around a software library, the NeuroML Development Kit (NDK), designed by Fred Howell and Robert Cannon to simplify the process of interacting with XML serializations of models; however, no particular structures were defined for use in describing models. Instead, users were free to invent their own structures and serialize them via the NDK, with a goal that some consensus would emerge around the most common structures used for describing models. In practice, few users developed or used such structures, hindering wider adoption.

Following discussions with Howell and Cannon about the need for a common data format

for describing widely used model components, Sharon Crook worked independently on a language for describing neuronal morphologies in XML, MorphML (Qi and Crook 2004). Similarly, while working with Angus Silver to develop neuroConstruct (see ► “neuroConstruct”), Padraig Gleeson developed a simulator-independent representation for morphologies, ion channels, and networks. It was agreed that these efforts should be merged under the banner of NeuroML, and the version 1.x structure of NeuroML was created (Gleeson et al. 2010). This version of the language was designed with three levels (incorporating MorphML, ChannelML, and NetworkML), allowing application developers to choose which parts of the language to support. XML schema files for this version of the standard have been available since 2006. As NeuroML documents became more widely used by multiple simulation platforms and visualization resources, there was a need for explicit, machine-readable descriptions of the mathematical details underlying the higher-level neuroscience-based components in NeuroML. Thus, in the latest version of NeuroML (version 2.0), the mathematical details of the neuroscience components are defined in a domain-independent XML-based language as described below.

NeuroML Structure

The structure of NeuroML is designed in a modular way and centers around objects based on high-level neuroscience concepts such as cells, channels, and synapses, which provide the core model types. This conceptual framework parallels the approach used to derive and define neuroscience models in the literature. NeuroML allows for descriptions of detailed neuronal morphologies and their electrical properties such as the passive membrane properties and the location and densities of active membrane conductances. The language also provides for the associated descriptions of the ion channel and synapse models, as well as three-dimensional neuronal network models based on these components. NeuroML also includes descriptions of single-compartment (point) neuron models that are

widely used in the literature and of networks of these more abstract neuron models. Additionally, structures for metadata can be used to annotate any NeuroML model.

Gleeson et al. (2010) provide an overview of the structure of NeuroML for version 1.x, as well as examples of its use, and testing of the mapping of NeuroML to multiple simulation platforms. With version 2.0, NeuroML underwent a major update to allow for greater extensibility of the language and to provide machine-readable definitions for the core model types. In this version, the structure and dynamical behavior of the core model types (ion channels, cells, synapses, current sources, etc.) are based on underlying definitions provided in LEMS (the Low Entropy Model Specification language) (Cannon et al. 2014). Developed by Robert Cannon, LEMS is a domain-independent XML-based language for specifying hierarchical mathematical models of physical entities. Applications which support NeuroML can choose to support only the set of high-level model concepts in the language (as was the case when supporting NeuroML version 1.x), or they may make use of the underlying mathematical definitions provided by LEMS and in this way support any new model types added in the future.

There are several additional advantages provided by using LEMS to describe the model component structure and dynamics that underlie each element in NeuroML. One is that this machine-readable format can be used to enforce correct handling of the dimensions for the physical variables in the model. Another is that LEMS facilitates the construction of models across spatial scales that include components developed within the systems biology community that are described in SBML (Hucka et al. 2003). This allows these two communities to exchange models, technical experience, and ideas. In addition, NeuroML version 2.0 is accompanied by a suite of application programming interfaces in Java (jNeuroML) and Python (pyNeuroML) that simplify the process of interacting with models that are expressed in NeuroML and LEMS. jNeuroML allows a user to validate, simulate, translate, and analyze models in NeuroML 2.0. pyNeuroML provides the same functionality in Python with a number of other features to convert, visualize, and analyze models.

NeuroML Community

Information about the NeuroML specification, libraries, and documentation is available at the NeuroML website (<https://www.neuroml.org/getneuroml>). A large number of software applications and tools provide some support for NeuroML. A list of these tools and their level of support also is available on the NeuroML website (https://www.neuroml.org/tool_support). Information about the application programming interfaces jNeuroML and pyNeuroML can be found in either of these locations. Examples of NeuroML models can be found at NeuroML-DB, a database of models in NeuroML format (<https://neuroml-db.org>), as well as Open Source Brain (<http://www.opensourcebrain.org>; ► “Open Source Brain”). The use of NeuroML as a standardized format for describing models allows for automated characterization of model behaviors at NeuroML-DB and for web-based model simulation, visualization, and analysis at Open Source Brain.

An elected editorial board guides the development of NeuroML. This board (<https://www.neuroml.org/editors>) consists of five members who define and document the core specification of the language, oversee tool development, maintain the website, and provide oversight of basic support for the further development of the NeuroML language.

electrical activity, canonically through metabotropic G-coupled protein receptors. In contrast to classical neurotransmission, which directly opens ion channels, neuromodulators can act either synaptically or extra-synaptically (e.g., hormonal pathways) to modify neuronal activity. Because neuromodulators can simultaneously target many neurons, our understanding of their function on networks has progressed furthest in small systems with known connectivity. In particular, much research has been conducted within invertebrate central pattern generator (CPG) networks. These networks exhibit spontaneous electrical discharges that drive rhythmic muscle contractions to produce simple behaviors such as chewing, breathing, and locomotion.

Definition

Neuromodulators are signaling molecules that induce long-lasting or network-wide changes in

Detailed Description

Neuromodulation, while often receiving less attention than direct synaptic communication between neurons, is a vital and ubiquitous feature of neuronal networks of all sizes. Modulation may be achieved by traditional small-molecule neurotransmitters, such as dopamine (DA) or GABA, or by small peptides and may act locally within a small network or globally across the entire nervous system. The diversity of function achieved by neuromodulation is a critical feature of neural systems that must be considered by computational neuroscientists as they strive to build accurate models of brain function.

Modulation can be distinguished from synaptic transmission by its limited spatial and temporal specificity. In the mammalian brain, modulatory substances such as dopamine, norepinephrine, histamine, serotonin (5-HT), and acetylcholine are broadly released by projections capable of producing lasting effects through much of the central nervous system (CNS) simultaneously. In smaller networks modulators can serve a similar function; they may be released locally to affect a small group of cells in a central pattern generator or may be released in a paracrine fashion or as circulating hormones, influencing computation at many foci.

Work done with invertebrate systems, especially those of central pattern-generating networks, has shown that modulatory substances can affect neural computation at essentially every level of function (Fig. 1), adding richness and flexibility to circuitry that is not readily apparent from even the most accurate map of synaptic connectivity. Modulation may act directly on membrane conductances in the soma or spike generating regions of neurons, driving oscillations or affecting changes in gain (Marder 2012). After action potentials are generated, neuromodulation can shape features of spike propagation in axons (Ballo et al. 2012). When these signals reach their targets, neuromodulation may again be present to modify information transmission both at synapses between neurons (Zhao et al. 2011; Marder 2012; Nusbaum and Blitz 2012) and at the final nervous system output to muscles (Brezina et al. 1996, 2000, 2003).

Furthermore, the application of a single modulator can affect multiple targets within a neuromuscular system. For example, the application of the neuropeptide myosuppressin elicits two dramatic effects on cardiac output in lobsters: a decrease in heart rate and an increase in cardiac muscle contraction force (Fig. 2a). The first effect appears to result from changes in the intrinsic dynamics of the cardiac CPG, which slows the rhythmic activity of motor neurons (Fig. 2b). The second effect stems from an increase in muscle sensitivity to neural input, perhaps by modulating the neuromuscular junction (Fig. 2c).

The diversity of modulatory targets, modulatory substances, and sites of modulatory action in the nervous system is striking and perhaps even staggering; evolution has evidently found heavily modulated neuronal environments advantageous, without regard for how difficult it might be to

that is subject to modulation from internal sources (cyan *synapse*). (d) A network that is affected by hormonally delivered neuromodulators. The entire system is bathed in low levels of modulator (cyan *background*), and individual components of the network that express receptors are specifically targeted (shown schematically as cyan *boxes*)

understand such networks as an observer. The task for the computational neuroscientist is to first understand the power of neuromodulation to affect networks at all levels and to consider that even at the level of relatively simple, small networks, modulation grants a much wider range of function, and significantly more computational power than can be otherwise achieved. This entry summarizes what is currently known about neuromodulation in the context of small invertebrate pattern-generating networks, with a focus on results which are relevant to the computational neuroscientist, especially those that involve explicit *in silico* investigation.

Neuromodulators Affect Neural Systems at the Network Level

Neuromodulation May Be Required for Network Output

While neuromodulation is classically thought to provide functional tuning to the output of pre-configured neuronal networks, in some cases, modulation is required for small pattern-generating networks to produce any functional output at all. This requirement may arise from either intrinsic modulation, in which the modulatory sources are located within the network itself, or from extrinsic modulation, in which modulatory signals originate from distal regions of the animal and may be released either locally or hormonally (Fig. 1).

Extrinsic Modulatory Requirement

In the stomatogastric ganglion (STG) of crustaceans, neuromodulatory inputs from anterior sources, such as the paired commissural ganglia (CoG), are required for the production of two rhythmic motor patterns which operate at different frequencies: the pyloric and gastric mill rhythms (Marder and Bucher 2007). When these inputs are severed or pharmacologically blocked, either the network falls completely silent or the frequency of these rhythms decreases substantially. One important target of this modulation is an excitatory inward current present in many stomatogastric

neurons known as I_{MI} (Swensen and Marder 2000, 2001). The activation of this current is necessary to induce spontaneous bursting in pace-maker cells, which drive the rest of the CPG network. This is a classic example of network reliance on extrinsic modulation.

Intrinsic Modulatory Requirement

In the *Tritonia* swim network, the dorsal swim interneurons (DSI) are part of the canonical CPG and participate in rhythm generation through direct ionotropic neurotransmission; however, they also signal through metabotropic receptors to modulate the strength of a synapse in the circuit between two other neurons known as VSI and VFN. Swimming behavior in this animal is an episodic response to sensory inputs, which involves a switch from a non-bursting to a transient bursting mode. A computational study that searched the space of parameters in a network constrained by the topology of the *Tritonia* swim CPG found that it is difficult to construct a network with static parameters capable of matching this *in vivo* behavior; most bursting models either were oscillatory indefinitely or produced intrinsic bursting without a sensory trigger (Calin-Jageman et al. 2007). Because both the bursting and non-bursting modes of this network are relatively stable, the intrinsic modulation is required to alter network parameters during canonical output, thus allowing the CPG to perform its function.

Neuromodulators Can Fine-Tune Network Output

In addition to providing a drive that may be essential for network function, modulatory substances often tune features of output more subtly. These tuning functions, especially when conferred by a diverse range of modulatory substances, grant substantial flexibility to networks that is often important for behavior, allowing output features to be adjusted without changing the canonical pattern. Two experimental systems have provided detailed examples of these modulatory tuning

controls, but these are representative of what is seen in all nervous systems.

Crustaceans In the STG of crabs and lobsters, a wide variety of modulatory substances are capable of influencing properties of the pyloric rhythm while maintaining its triphasic output pattern (Marder and Bucher 2007). A detailed investigation of modulation of the various cells of the pyloric CPG found that while many different modulators converge on the same inward current (I_{MI}) in different neurons, the subset of circuit neurons upon which each substance acts is different (Swensen and Marder 2000). Thus, each

modulator is capable of influencing the network in a slightly different manner, producing distinct outputs that vary in features such as spikes per burst of motor neurons and phase relationships (Marder 2012). The ability of targeted modulation to evoke different versions of the pyloric rhythm was experimentally verified in a dynamic clamp study, in which the modulatory input current was computationally simulated in a neuron called PY while a modulator that does not affect this current was bath-applied to the STG. This manipulation was able to mimic the network effects of a different modulator which biologically turns on the equivalent current in PY (Swensen and Marder 2001).

Neuromodulation in Small Networks,

Fig. 2 Crustacean myosuppressin (a peptide hormone) modulates the cardiac system at multiple sites (All data are reproduced, with permission, from Stevens et al. (2009)). (a) The effect of myosuppressin in semi-intact heart preparations, in which motor neuron activity and muscle output are simultaneously recorded. Myosuppressin elicits a decrease in heart rate and an increase in cardiac muscle contraction force. (b) The effect of myosuppressin on the isolated cardiac ganglion, which contains the cardiac CPG. Myosuppressin elicits a decrease in motor neuron burst frequency, which appears to be responsible for the decrease in heart rate in panel A. (c) The effect of myosuppressin on a stimulated cardiac muscle preparation. Myosuppressin increases contraction force to the same electrical stimulation, which appears to be responsible for the increase in muscle contraction amplitude in panel A

Another well-studied crustacean motor circuit is the cardiac ganglion, which controls the frequency and strength of heart contractions. Neuromodulators are delivered to this system hormonally through the hemolymph or directly through extrinsic nerve fibers from the central nervous system. These modulators fine-tune both heart rate and cardiac muscle contraction force to meet behavioral demands (Fig. 2; Cooke 2002), for example, by eliciting an increase in heart rate when lobsters run on an underwater treadmill (Guirguis and Wilkens 1995).

Mollusks Well-studied modulated small networks also exist in mollusks, such as the snail *Lymnaea* and the sea slug *Aplysia*. An extensively studied CPG controls feeding behavior in *Aplysia* by operating a sequence of muscle contractions important for both ingestive and egestive feeding behavior (Cropper et al. 2004). A diverse set of neuropeptides have been characterized which shape a number of features of this network, including activation of fictive feeding patterns in quiescent preparations (Sweedler et al. 2002) and inhibition of motor neuron spiking (Furukawa et al. 2001). Neuropeptides also inhibit muscle contraction in the periphery at both the esophagus and stomach (Fujisawa et al. 1999; Furukawa et al. 2001).

This modulation can also alter the specific details of the neuromuscular transform at these output synapses. The neuromuscular junction of the *Aplysia* accessory radula closer (ARC) muscle is modulated by an extensive array of modulatory neuropeptides released from interneurons and sensory neurons, which provide the ability to tune various features of this function. These substances act presynaptically to regulate the release of ACh onto muscles to initiate contraction and also act through G protein-coupled receptors to alter many features of muscle contraction such as latency, amplitude, and relaxation rate (Brezina 2010). This scenario gives the animal extensive control despite the paucity of direct innervation; only two motor neurons innervate the ARC muscle. A semi-realistic model containing interactions

between neurons, modulators, and musculature at the periphery argues that modulation improves performance and appears to be required for the range of spiking behaviors, both regular and irregular, apparent in the biology (Brezina et al. 2005). This work again emphasizes the important function of modulation to give networks the ability to more flexibly control output than is possible with fixed network parameters.

Neuromodulators Can Switch Network Modes and Circuitry Through Multiple Mechanisms

Neuromodulation is also able to switch small neural networks between multiple modes, allowing for a much greater flexibility and diversity of responses than is obvious only from considering the connectome, or connectivity, of the system.

In *C. elegans*, the entire wiring diagram of the nervous system is known from electron micrograph reconstructions; a description of the connections among the 302 neurons was published decades ago (White et al. 1986). Yet it remains difficult to reliably identify important features of network function, due to the presence of extensive neuromodulation. More than 200 neuropeptide genes have been identified, the protein products of which actively reconfigure circuitry in response to sensory stimuli and environmental factors (Bargmann 2012). This modulation affects circuitry in a variety of ways. In one example, octanol avoidance in well-fed animals is mediated by a nociceptive sensory neuron called ASH. Following starvation, octanol avoidance behavior becomes distributed among three nociceptive neurons (Chao et al. 2004). The well-fed state can be mimicked by exogenous application of modulatory substances such as serotonin, dopamine, octopamine (OA), and some neuropeptides (Horvitz et al. 1982). In addition to influencing which neurons participate in particular behaviors, the same neuron may play a role in strikingly different behaviors depending on modulatory tone. The aforementioned ASH neuron, for example, is also capable of driving social aggregation

behavior, but does so only when the activity of a modulatory neuropeptide, *npr-1*, is low (Bargmann 2012). Thus, the well-known wiring diagram in this species serves more as a starting point for analysis of functional circuitry than an end, as which connections are active and important at any given time depends extensively on neuromodulation.

In the mollusk *Aplysia*, the feeding CPG network also features modulation that switches the modes of network output. Here, the same underlying circuitry supports both ingestive and egestive feeding behavior, and the expression of either depends heavily on neuromodulation. Neuropeptides have been implicated in biasing network output for either ingestion or egestion (Jing and Weiss 2001; Kupfermann and Weiss 2001; Morgan et al. 2002), and even thought to play a more direct role in network switching (Vilim et al. 2010). Vilim et al. (2010) showed that two structurally related peptides have distinct actions on neurons in the network, yet can work together to cause a switch between these two network modes and to depress contractions in feeding muscles.

The idea that neuromodulation can switch small rhythmic networks between operational modes was investigated in a recent modeling study using a reduced model system motivated

by the linked oscillators present in the STG. Gutierrez et al. (2013) created a simplified network of model neurons in which two oscillatory pairs of neurons, one with a fast period and one with a slow period, were coupled through a “hub” neuron, which was capable of oscillating in time with either pair (Fig. 3a). The authors found that there were many potential targets within the network at which modulation influenced the behavior of the hub neuron. Significantly, the three entirely different circuit mechanisms could switch the hub neuron from oscillating with the fast pair to oscillating with the slow pair (Fig. 3b–d). Altering network parameters is a key feature of neuromodulation, as is a diversity of targets within neural systems, and thus this work implies that neuromodulation is likely to be a key player in networks that feature the coupling of multiple oscillatory units.

Variability and Robustness of Neuromodulatory Signaling

An essential requirement of neuronal systems is to produce robust behaviors despite the intrinsic variability and randomness of biological systems (Marder and Goaillard 2006). Many network

N

Neuromodulation in Small Networks, Fig. 3 Computational model of switching network behaviors with neuromodulation. (a) The “baseline” model network, consisting of five oscillating cells. The hub neuron (hn, in green) oscillates at the frequency of the slowly oscillating half center (s1 and s2, in blue), twice as slow

as the quickly oscillating half center (f1 and f2, in red). (b–d) Three example circuit manipulations, which may be induced via neuromodulatory mechanisms, which switch the behavior of the hub neuron to oscillating at the frequency of the fast half center (Figure reproduced from Gutierrez et al. (2013))

parameters vary over severalfold ranges: the maximal conductances of ionic currents, the strength of chemical synapses, and the strength of modulator-invoked currents (Marder and Taylor 2011; Roffman et al. 2012). This variability is not entirely random: it may result from homeostatic regulation mechanisms that tune intrinsic conductances and synaptic strengths such that functional output is maintained despite stochastic channel turnover and environmental perturbation (O'Leary and Wyllie 2011; Williams et al. 2013b). The inherent variability in the underlying structure of CPGs poses a problem for robust modulation, because altering network properties will yield variable effects depending on the initial parameters of the circuit (Grashow et al. 2009).

Most commonly, the effects of neuromodulators are qualitatively robust but quantitatively variable; neuromodulators generally affect measures of network activity in the same direction, but the magnitude of these effects is variable. In many cases the variability in a neuromodulatory effect is correlated with visible characteristics of baseline network activity. For example, in rhythmically bursting leech heart interneurons, the application of myomodulin usually increases burst frequency and intra-burst spike frequency; the magnitude of this change ranges from 0% to 50% across preparations and is correlated with the baseline frequency and intra-burst spike frequency of the rhythm (Tobin and Calabrese 2005). In another example from the crustacean STG, a number of neuromodulators produce consistent increases in the cycle frequency of the pyloric CPG upon their application, but these effects are only significant when the initial frequency of the pyloric rhythm is low (Nagy and Dickinson 1983; Nusbaum and Marder 1989; Skieba and Schneider 1994; Fu et al. 2007; Ma et al. 2009). These results have an intuitive explanation: the excitatory effects of a modulator can saturate when the system is already excited to begin with (similarly, the firing rate of a spiking neuron will saturate at some frequency due to the absolute refractory period). Additionally, the saturating nature of these modulators is sensible from a design perspective, because they can function to stabilize network output within physiologically useful bounds (Marder 2012).

A number of other experiments have reported more perplexing results, in which modulators do produce qualitatively distinct effects on network activity across preparations. Wiwatpanit et al. (2012) reported that the application of the neuromodulatory peptide C-type allatostatin (C-AST) to the heart of the lobster *Homarus americanus* produced a continuum of effects on the peak contraction force of the cardiac muscle. In some preparations, C-AST produced a significant decrease in peak force, in others it produced increases in peak force, in still others it showed biphasic responses in which peak contraction force first decreased, and then steadily increased over time; and sometimes no effect was observed at all (Wiwatpanit et al. 2012). A recent study showed that these qualitatively opposing results arise not only from variability in the effects of AST-C but from the nonlinear neuromuscular interface and variability in baseline CPG activity (Williams et al. 2013a).

Similar inconsistencies were observed in the STG of the spiny lobster *Panulirus interruptus*. Here, bath application of 5-HT produced a substantial increase, decrease, or no change at all in the cycle frequency of the pyloric rhythm, variability which was linked to the expression levels of different 5-HT receptors (Spitzer et al. 2008). These results are less intuitive from a design perspective, which provides an opportunity for theoretical work to bring clarity to these issues.

Interactions Between Neuromodulators

Due to experimental constraints, it is common for researchers to characterize neuromodulators one at a time, under controlled conditions. This does not, however, capture the complexity of biological systems, in which many different modulators are simultaneously present. The surprisingly large number of neuropeptide modulators has given rise to the field of neuropeptidomics, which seeks to characterize all bioactive peptides for a given species. Using mass spectrometry and transcriptome mining techniques, 31 families of crustacean neuropeptides have been identified, some of which contain over two dozen isoforms within

a single species (Christie et al. 2010). Genetic techniques have identified large numbers of neuropeptides in *C. elegans* (Husson et al. 2007; Li and Kim 2008) and *D. melanogaster* (Clynen et al. 2010). Additionally, modulatory neurons can co-release several modulators or transmitters onto one or more neural targets (Nusbaum et al. 2001). How can we extrapolate results from carefully controlled, in vitro experiments on neuromodulation to understand the messier organization of real biological systems?

Modulators Act Through Convergent and Divergent Chemical Signaling Pathways

Understanding the interactions of multiple signaling molecules is a difficult but frequently studied problem within the field of systems biology (Boonen et al. 2009). Within this conceptual framework, neuromodulators, including neurotransmitters, hormones, and growth factors, form complex signaling networks that both diverge and converge (Fig. 4). A signaling pathway is said to branch or diverge when an upstream element acts on multiple downstream targets, such as a modulator that binds to two different receptors. Different pathways are said to converge when two or more upstream elements act on the same downstream target, for example, two different modulators that activate the same signal transduction pathway. In general, upstream elements can either activate or repress downstream targets. Given the complexity of such signaling networks (Fig. 4a), and the nonlinearities inherent in biochemical processes and electrical signaling in neurons, it is unsurprising that the effects of multiple neuromodulators on network activity are not simply additive (Mesce 2002).

Neuromodulatory signaling pathways have been shown to converge on common targets in many vertebrate and invertebrate systems (Kaczmarek and Levitan 1987). In the crustacean STG, at least six different modulators activate the same voltage-dependent current (see Fig. 4b; Swensen and Marder 2001). Thus, when two of these modulators are applied in high

concentrations to isolated cells, they can occlude each other's effects. There are two points that may be drawn from these observations. First, the simultaneous application of several modulators can produce saturating effects due to convergence; it is possible, therefore, that convergence is a mechanism that safeguards the network from overmodulation (Marder 2012). Second, neuromodulatory signaling pathways exhibit degeneracy, defined as the ability for distinct elements to elicit the same functional output (Tononi et al. 1999). Degeneracy within a system is thought to contribute to its robustness, for example, by providing the ability to withstand partial deletions, and its evolvability, by allowing changes to be functionally incorporated (Whitacre 2010).

Individual modulators can also simultaneously tune multiple network parameters through divergent signaling pathways. For example, dopamine activates five different currents in the anterior burster neuron of the crustacean STG (Fig. 4c; Harris-Warrick et al. 1998; Harris-Warrick and Johnson 2010). Divergence may be advantageous in two respects. First, divergent structure increases the computational complexity and capabilities of the signaling network. Effectively, this structure stores information about how the neuronal circuit should be tuned in response to changing levels of a neuromodulator (Brezina and Weiss 1997; Brezina 2010). Divergence may also provide the network with a stability mechanism by scaling parameters with opposing effects. For example, dopaminergic modulation of the STG has been shown to activate both inward and outward currents across different cells in the circuit. Harris-Warrick and Johnson (2010) have suggested that this balance may allow dopamine to alter the bursting activity of STG neurons without depolarizing or hyperpolarizing the cells too much, which could either cause them to firing tonically or fall silent (Harris-Warrick 2010).

Nonlinear Interactions Between Modulators

In theory, the structure of neuromodulatory signaling pathways can accommodate many

a. Idealized Modulatory Signaling Network

c. Effects of Dopamine on the AB neuron in the STG

b. Modulatory Control of I_{MI} in the LP neuron of the STG

d. Control of the ARC muscle in Aplysia by two modulators

Neuromodulation in Small Networks, Fig. 4 Modulatory signaling pathways contain convergent and divergent structure. (a) A schematic diagram showing two hypothetical modulators that exert physiological changes through G protein-coupled receptors. These biochemical pathways contain divergent (example labeled “div.” in purple) and convergent (example labeled “con.”) pathways. In principle, it is possible for modulatory pathways to include feedback and autoregulatory connections (in gray), but these possibilities are poorly understood within the current literature. (b) An example of

convergence in crustacean STG: six different modulators converge to activate the same voltage-dependent current in the lateral pyloric (LP) neuron (see Swensen and Marder 2000). (c) An example of divergence in the crustacean STG: the application of one modulator (dopamine) alters the activity of five different ionic currents (see Harris-Warrick et al. 1998). (d) The signaling pathways of two neuropeptides that affect the contraction dynamics of the ARC muscle in Aplysia contain convergent and divergent connections (see Brezina et al. 1996)

complex and nonlinear interactions between modulators (Brezina and Weiss 1997; Alon 2006). However, relatively few studies have directly examined combinatorial interactions between

different neuromodulators. Preliminary results, however, suggest that interactions between modulators can produce complex and behaviorally relevant effects:

- In the pre-Bötzinger complex of mice, the pharmacological blockade of the excitatory modulator substance-P produces little to no response, as long as two other excitatory modulators, serotonin and noradrenaline, are present. However, during the chronic blockade of serotonergic and noradrenergic receptors, the acute blockade of substance-P produces significant decreases in respiration frequency (Doi and Ramirez 2010).
- In the cardiac sac of the spiny lobster *Panulirus interruptus*, the application of the neuropeptide proctolin alone does not induce rhythmic bursting. However, the application of red pigment-concentrating hormone (RPCH) appears to potentiate the effects of proctolin, allowing it to elicit a strong motor pattern. This can occur even when RPCH is applied at low, subthreshold levels (Dickinson et al. 1997).
- In the medicinal leech (*Hirudo medicinalis*), fictive swimming motor patterns can be induced by the application of either serotonin or octopamine, and this effect is lost when the modulator is washed out of the preparation. However, the reverse effect is observed when both modulators are simultaneously applied. During the initial application of both modulators, little to no fictive swimming patterns is produced, but upon washout of the modulators, strong rhythmic pattern is observed (Mesce et al. 2001).
- In the moth *Manduca sexta*, heart rate is controlled by a variety of neuromodulators including the excitatory modulators octopamine and type-2 cardioacceleratory peptides (CA₂). The application of octopamine at subthreshold levels substantially potentiates the heart's response to CA₂, but the subthreshold application of CA₂ does not significantly affect the heart's response to octopamine (Prier et al. 1994).
- A study of neuromuscular transmission in the yellow crab *Eriphia spinifrons* and the crayfish *Procambarus clarkia* showed that the application of octopamine consistently lessened the excitatory effects of 5-HT, even though octopamine alone produced variable effects across preparations, either increasing or decreasing transmission (Djokaj et al. 2001).

What mechanisms can explain these interactions between modulators? It is possible that different modulatory pathways interact directly through excitatory and repressive connections between their signaling cascades, similar to other chemical signaling networks that have been extensively investigated in *E. coli* (Alon 2006). While this possibility is of outstanding interest, it has not been seriously tested to date, because neuromodulatory signaling pathways in small invertebrate networks are not well-characterized.

Even without direct chemical interactions, the complexities inherent within neuron membrane dynamics admit the possibility of nonlinear interactions between modulators. Goldman et al. (2001) examined this second possibility in a conductance-based model neuron and in biological STG neurons. By simulating the activity of the model neuron across many different maximal conductance combinations, they constructed a map of neural activity across a conductance space (Fig. 5a). A similar (but more restricted) map was experimentally determined by varying maximal conductance parameters of injected dynamic clamp currents (Fig. 5b). Within both of these maps, each point represents a different set of maximal conductances, the activity pattern of the neuron at that point is represented by its color, and the effects of a modulator can be visualized as a vector that moves the model from one point to another. This serves as a simple, but useful, approximation of biological modulation as modulators can have many other effects in addition to changing the maximal conductance of an intrinsic current. In Fig. 5, the black arrows show the effects of a modulator that largely preserves neural activity, in what Goldman et al. (2001) refer to as an insensitive direction of modulation. In contrast, the modulatory shift denoted by the green arrow qualitatively changes the behavior of the model cell, considered a sensitive direction of modulation. In Fig. 5b, note that the black modulator can shape the effect of the green modulator in a nonlinear fashion: the green modulator produces tonic spiking behavior when applied alone, but produces bursting behavior when co-applied with the black modulator. This result stems from the fact that the boundaries between qualitatively

Neuromodulation in Small Networks, Fig. 5 Neuromodulators can tune network parameters in sensitive (*green arrows*) and insensitive (*black arrows*) directions through global parameter space (Data is reproduced, with permission, from Goldman et al. (2001)). (a) A global activity map of a single-compartment

model neuron when the maximal conductances of three voltage-dependent currents are independently varied. Each dot illustrates the activity pattern of the neuron in that region of parameter space. (b) A similar activity map for a biological neuron when the strength of two dynamic clamp currents is altered

different activity patterns in conductance space are curved (i.e., nonlinear).

How Many Modulators Are Needed to Control Network Output?

Modulators can alter the activity of individual neurons and connected networks, but to what degree can they precisely control this output? Within the parameter space of a circuit, the effects of a single neuromodulator can be visualized as pushing the network along a one-dimensional path. In Fig. 5, we approximated these paths as vectors, but these paths would be more realistically captured as nonlinear curves (see Brezina and Weiss 1997). Additionally, these curves would have finite length since the effects of a modulator saturate at high concentrations. This one-dimensional case can be easily generalized. The coordinated actions of two neuromodulators can move the system along a finite, two-dimensional surface in parameter space. This is analogous to two linearly independent vectors that define a 2D plane; when the two modulators are combined at different concentrations, the network is moved in a unique direction

within a 2D region of space. In general, a system with N distinct modulators can independently control the parameters of the network within a finite N -dimensional region (Brezina and Weiss 1997). Equivalently stated, a neuromodulatory system requires at least N distinct modulators to independently control N different network parameters. However, modulators may hold less combinatorial power in practice, as they may be co-released under naturalistic conditions (Nusbaum et al. 2001).

One notable experimental study on the accessory radula closer (ARC) muscle of *Aplysia* supported this basic theoretical framework; the authors demonstrated that two features of muscle output, the amplitude and relaxation rate of muscle contractions, could be independently controlled by changing the relative concentrations of two neuropeptide signals (Brezina et al. 1996). Because small neuronal networks tend to be influenced by many different neuromodulators, it is possible that modulatory systems are designed to have broad control over network parameters (Brezina 2010). However, the extent of neuromodulatory control over circuit parameters remains an open experimental question in many systems.

Implications for Modeling

The extensive study of neuromodulation in small, pattern-generating invertebrate networks has led directly to modeling work described here and must also serve to inform modelers as they grapple with future issues, particularly in light of recent focus on obtaining the synaptic wiring diagram from more complex systems. While there is a wealth of invaluable information present in the connectome, when similar “wiring diagrams” of neuromodulation have been attempted, the results can be at least as complex, even in small systems (Brezina 2010). The extensive convergence and divergence of modulator actions, the huge number of modulatory substances, and the wide variety of cellular and network properties which are thereby affected amount to a staggering amount of complexity and flexibility which allows even very small networks to perform a variety of highly tuned and behaviorally relevant functions. Further, these actions and substances still elude complete description, as even in very well-studied systems, entire new families of modulatory neuropeptides are still being discovered.

A thorough consideration of the full richness of modulation will serve computational neuroscience well: their intrinsic and extrinsic origins; their diverse site of action, at every level of neuronal computation; their ability to gate network output entirely or simply fine-tune it; their extensive overlapping convergence and divergence; and their complicated interactions and modulatory connectome. All of these important features of neuromodulation are present even in small networks and are critical to reaching a proper theoretical understanding of circuit function both at this level and at the level of the entire nervous system.

Neuromorphic Cognition

Giacomo Indiveri and Rodney Douglas
Institute of Neuroinformatics, University of
Zürich and ETH Zürich, Zürich, Switzerland

Synonyms

Neuromorphic cognitive systems; Neuromorphic electronic systems; Neuromorphic real-time behaving systems

Definition

The hallmark of cognitive behavior is the ability of an agent to select an economically advantageous action based on immediate external stimuli as well as on their longer-term context. Neuromorphic cognition refers to the cognitive abilities of systems or agents implemented in neuromorphic electronic VLSI technology whose processing architecture is similar to the distributed, asynchronous one of biological brains. Neuromorphic agents are typically real-time behaving systems composed of multiple asynchronous event-based VLSI chips that integrate networks of silicon neurons and dynamic synapses together and that are interfaced to event-based neuromorphic sensors and robotic actuators. In order to express cognitive performance, these agents require a hardware infrastructure that supports local learning and decision making, for distributed communication and for the elaboration of state-dependent processing. We describe examples of such mechanisms and present a method for efficiently implementing neuromorphic cognition in these agents.

Detailed Description

Digital computers provide prodigious computational power and memory for the simulation of models of cognition. Nevertheless humans and many animals including insects still outperform the most powerful computers in real-world cognitive tasks. This disparity between the effectiveness of biological nervous systems and computers is primarily attributable to differences in their elementary processing devices and to the kinds of computational primitives they implement (Indiveri and Horiuchi 2011; Mead 1990). Rather than using Boolean logic, precise digital representations, and clocked operations, the nervous systems perform robust and reliable computation using hybrid analog/digital unreliable components; they employ distributed, event-driven, collective, and massively parallel mechanisms, and they implement adaptation, self-organizing, and learning strategies, on multiple spatial and

temporal scales. Understanding these principles, and how they can lead to behaviors that exhibit cognitive qualities, remains a major challenge for science.

The goal of *neuromorphic cognition* is to understand the neural mechanisms used by the brain to achieve cognition, as well as to implement them using electronic neural systems whose physics of computation and architectural constraints are based on those of the biological nervous systems. During the last decade the neuromorphic engineering community has made substantial progress in this endeavor by designing *neuromorphic sensors* and *neuromorphic hardware* and *spiking neural networks* and by developing the platform technology necessary for constructing distributed multi-chip systems of sensors and neuronal processors that operate asynchronously and communicate using action potential like signals (or spikes) (Chicca et al. 2007b; Merolla et al. 2007). In particular, it is now possible to build large multi-chip neuromorphic systems that combine multiple sensors with spiking neural network chips, robotic actuators, and end-effectors, as well as with conventional digital computing systems (e.g., for data logging, or further analysis). Usually, each chip specializes in a specific neural function (such as visual sensing, auditory sensing, filtering, spike-based learning).

The ability to construct distributed systems from collections of heterogeneous neuromorphic subsystems is largely due to the development of a very simple communication scheme, the “address-event representation” (AER), that is analogous to action potential communication between biological neurons. In AER, signal sources (such as silicon retina pixels or silicon neurons) each have a unique address. They signal their current activation by transmitting their address asynchronously on a digital bus. These AER events can then be routed to various target processors, in an analogous manner to axons routing somatic spikes to synapses.

Until recently, systems of this type have been mainly reactive, responding directly to stimuli with less regard for their embedding context in

either the observed world or within the economic goals of the agent. This limitation has been due to their inability to autonomously extract, and reason over, more sophisticated models of world and self, abilities that are characteristic of *cognitive* systems. The step from reaction to cognition in neuromorphic systems is not an easy one, because the principles of cognition remain to be unraveled. Discovering these principles, and learning how to implement them in neuromorphic technology, is now an active domain of research. For example, considerable effort is devoted to developing electronic circuits that are considered to provide “necessary conditions” for cognition, such as the abilities to:

1. Interact with the environment efficiently in real time, with appropriate temporal dynamics.
2. Store memories and to learn about the nature and statistics of their input signals.
3. Make weighted decisions.
4. Generate appropriate sequences of behavior.

These are only necessary conditions. To build neuromorphic cognitive systems, the challenge is not only to develop the appropriate hardware circuits and systems but more generally to understand what kinds of computational models asynchronous spiking neurons can support and how to configure the hardware neurons to perform desired tasks using a particular computational approach. Recent projects have obtained promising results in this direction (Eliasmith et al. 2012; Giulioni et al. 2011; Indiveri et al. 2009; Neftci et al. 2013). For example, an important recent result offers a foundation for the design and construction of compact and effective cognitive neuromorphic systems (Rutishauser and Douglas 2009). These authors describe how state-dependent computation can be designed using coupled recurrent networks. In the next sections we will first present examples of basic neuromorphic building blocks that can be used for implementing the necessary conditions. Thereafter we describe a method that uses these building blocks and the principles of (Rutishauser and Douglas 2009) to “synthesize” a simple cognitive agent.

Temporal Dynamics in Neuromorphic Systems

Neuromorphic architectures and processing strategy are substantially different from those of conventional von Neumann computers. The von Neumann architecture calls for a small number of complex processors, which are each able to access a very large common memory storing code, data, and partial results. Memory access and the processing of that data are highly orchestrated, occurring synchronously at very high clock rates. The processors are time multiplexed, computing on partial results that must be transferred from and to the external memory banks.

By contrast, neuromorphic spiking neural network architectures are composed of massively parallel arrays of simple processing elements in which memory and computation are co-localized. This design does not allow for the virtualization of time and the rapid transfer of partial results back and forth between the computing units and memory banks situated outside the architecture core. Instead, the synapse and neuron circuits of neuromorphic architectures must process input spikes on demand, as they arrive, and must produce their output responses in real time. Consequently, the processing elements must operate with time constants that are well matched to those of the natural world signals they are designed to process. This constraint is not easy to satisfy using conventional analog VLSI circuits, whose transistors operate in the *strong-inversion regime* (Sze 1981), because the demand for long time constants can lead to area-expensive solutions. The area cost can be avoided by neglecting the requirement for matching and modeling the neural dynamics instead at accelerated, unrealistic time scales (Brüderle et al. 2011; Schemmel et al. 2007; Wijekoon and Dudek 2008). An alternative solution to this problem is to use current-mode design techniques (Tomazou et al. 1990) and log-domain circuits operating in the *weak-inversion regime* (Liu et al. 2002). The time constants of these circuits are proportional to the circuit capacitance and inversely proportional to a reference current. If the reference current is a subthreshold one, then this current can be as small

as fractions of pico-amperes. Time constants of milliseconds would therefore require capacitors of only femtofarads, which can be implemented with very compact designs in standard VLSI technologies. Following this approach it is possible to build compact low-power neuromorphic circuits that can faithfully reproduce the dynamics of synaptic transmission observed in biological synapses (Destexhe et al. 1998) and that can implement sensory and signal processing systems for agents that need to interact with the environment in real time (Liu and Delbruck 2010).

An example of a compact subthreshold log-domain circuit that has often been used to reproduce biologically plausible temporal dynamics is the differential pair integrator (DPI) (Bartolozzi and Indiveri 2007). Using log-domain circuit analysis (Bartolozzi and Indiveri 2007; Drakakis et al. 1999; Frey 1993), and with reasonable assumptions of non-negligible input currents (Bartolozzi et al. 2006), it can be shown that the DPI circuit is equivalent to a first-order linear integrator which faithfully reproduces the dynamics of synaptic transmission observed in biological synapses (Destexhe et al. 1998).

Spike-Based Learning and Plasticity Mechanisms

One of the key properties of cognitive neural systems is their various forms of *plasticity*. In particular, “long-term” plasticity (Abbott and Nelson 2000) can produce sustained changes in the strength of individual synapses and so learn about the state of the environment.

Implementations of *long-term* plasticity mechanisms in neuromorphic VLSI chips provide a method of self-calibration, by which synaptic weights can be set automatically, without the overhead of dedicated wires and pins that would be required to load individual synapses from an external source.

Fortunately, plasticity mechanisms based on the timing of the spikes map very effectively onto silicon neuromorphic devices (Fusi et al. 2000; Häfliger et al. 1997; Indiveri et al. 2006; Mitra and Indiveri 2009; Bofill-i Petit and Murray

2004). A popular class of spike-driven learning rules is based on the spike-timing-dependent plasticity (STDP) (Abbott and Nelson 2000; Markram et al. 1997). In STDP the relative timing of pre- and postsynaptic spikes determines how the efficacy of a synapse is updated. There are several implementations of STDP learning chips (Arthur and Boahen 2006; Indiveri et al. 2006; Mitra and Indiveri 2009; Bofill-i Petit and Murray 2004), and a wide range of theoretical models have been proposed. Both the theoretical models and the VLSI implementations indicate that STDP can be effective in learning to classify spatiotemporal spike patterns (Arthur and Boahen 2006; Gütiç and Sompolinsky 2006), although, in its simplest form, the STDP algorithm is unsuitable for learning different patterns of mean firing rates (Abbott and Nelson 2000).

An interesting issue that arises for physical implementations of plasticity mechanisms, be they biological or electronic, is that the synaptic weights they update are both bounded (they can neither increase indefinitely nor assume negative values) and have limited resolution. This restriction on the precision and range of the weights imposes strong constraints on the network's capacity to store and retain synaptic memories. For example, in attractor networks with bounded synapses (Giulioni et al. 2011), if the long-term changes in synaptic weight cannot be arbitrarily small, the network's memory trace decays exponentially with the number of stored patterns.

In addition to the problem of overwriting the stored synaptic values with new ones, neuromorphic VLSI implementations must also address the problem of possible decay of the stored synaptic weight voltages with time (e.g., due to leakage). One effective strategy for protecting stored memories against decay is to permit only two stable synaptic efficacy states per synapse and allow only a very low average number of transitions from one stable state to the other (Fusi 2002). By modifying only a random subset of the synapses with a small probability, memory lifetimes increase by a factor inversely proportional to the probability of synaptic modification (Fusi 2002).

Given a stochastic mechanism for the weight update, and provided neurons are stimulated via a large number of redundant synaptic circuits, hardware implementations of spike-based learning networks can be shown to have computational properties analogous to the ones of ideal networks, with unbounded synapses (Fusi 2002). Where neuromorphic sensors interface with the environment, the input signals are inherently noisy. The noise of these input spike patterns is sufficient to drive the stochastic update mechanism required to increase memory lifetimes. In addition, by permitting only two stable synaptic states to store on long time scales the values of the weights, it is sufficient to use a bistable circuit that restores the synaptic state to either its high rail or its low one, depending if the weight is above or below a set threshold. In this way memory is preserved even in the absence of stimuli or when the presynaptic activity is very low.

Brader and colleagues (Brader et al. 2007) have proposed a spike-based learning rule using bistable synapses that is able to classify patterns of mean firing rates. This model is also able to account for classical STDP behavior, as well as the additional rich phenomenology observed in neurophysiological experiments on synaptic plasticity. This rule has been implemented using neuromorphic analog/digital circuits (Chicca et al. 2013) and has been applied to real-time spike-based learning and classification (Giulioni et al. 2009, 2011; Mitra et al. 2008).

Soft Winner-Take-All Circuits

Winner-take-all (WTA) networks are well suited for implementing decision making and context-dependent action selection operators and are easily implemented using neuromorphic circuits. These types of networks typically consist of a group of interacting neurons that compete with one another in response to an input stimulus. The neurons with the strongest responses suppress competing neurons to win the competition. Competition is achieved through a recurrent pattern of connectivity involving both excitatory and inhibitory connections. Cooperation between neurons

with similar response properties (e.g., close receptive field or stimulus preference) is mediated by excitatory connections. Competition and cooperation make the output of individual neuron depend on the activity of all neurons in the network and not just on its own input. According to the relative strengths of recurrent excitation versus inhibition, the network may select only one winner (hard winner-take-all) or a small population of likely winners (soft winner-take-all) (Amari and Arbib 1977; Dayan and Abbott 2001; Hansel and Sompolinsky 1998; Wilimzig et al. 2006). WTAs are useful computational primitives because they perform linear operation such as amplification and locus invariance, as well as nonlinear operations such as selective amplification (or selective suppression) and multi-stability (Chicca et al. 2007a; Douglas and Martin 2007; Hahnloser et al. 2000).

The computational abilities of sWTA networks have been used for solving feature extraction and pattern classification problems in simulation (Ben-Yishai et al. 1995; Bennett 1990; Pfeiffer et al. 2010) and in neuromorphic VLSI (Chicca et al. 2007b; Hahnloser et al. 2000). Interestingly, the pattern of connection of the WTAs is consistent with the pattern of connections observed in

the superficial layers of the neocortex (Binzegger et al. 2004; Douglas and Martin 2004), suggesting that the neurons of these layers may make use of this computational primitive (Douglas et al. 1995; Somers et al. 1995).

The examples of WTAs listed above make use of continuous valued outputs that can be interpreted as discharge rates. However, in neuromorphic implementations, where communication is usually by spikelike address events, it is more convenient (and more biologically correct) to implement these primitives using spiking neurons. Several examples of VLSI sWTA networks of spiking neurons can be found in the literature (Abrahamsen et al. 2004; Chicca et al. 2004; DeYong et al. 1992; Hylander et al. 1993; Indiveri et al. 2001; Oster and Liu 2004). Figure 1 shows experimental data measured from one of such neuromorphic WTA networks (Chicca 2006; Chicca et al. 2004). This example shows how the VLSI spiking neural network can perform nonlinear selection. An input stimulus (see Fig. 1a) consisting of Poisson trains of spikes, with a mean frequency profile showing two Gaussian-shaped bumps with different amplitude, is applied to the input synapses of each neuron in the soft WTA network. The chip output response

N

Neuromorphic Cognition, Fig. 1 Raster plot and mean frequency profile of input stimulus (a) and sWTA network response (b). The input stimulus (a) consists of Poisson trains of spike; the mean frequency profile over neuron address shows two Gaussian-shaped bumps of activity with different amplitude. (b) The sWTA network chip

response shows how the bump with higher amplitude is selected and amplified while the other one is suppressed. The response of the pure feed-forward network (no sWTA dynamics) to the input is shown for comparison (thin trace in the mean frequency profile)

is a series of spike trains produced by the output silicon neurons (see Fig. 1b). The mean frequencies measured from each spike raster in Fig. 1b show how the soft WTA network selects and amplifies the Gaussian bump with higher activity while suppressing the other one, with respect to the baseline condition.

Synthesizing Cognition in Neuromorphic Architectures

The previous sections described examples of circuits and circuit design techniques that can be used to implement the necessary components for endowing neuromorphic systems with cognitive abilities. Neftci and colleagues have recently described a method that combines many of these elements into a neuromorphic agent able to express simple real-time cognitive behaviors (Neftci et al. 2013).

Their method recognizes three conceptual layers of processing: firstly, a high-level *behavioral* model, in which the target cognitive task is cast as a state machine that captures the state-dependent organization of the required behavior (Fig. 2b); secondly, an intermediate abstract *computational* layer, comprising a field of neurons configured as many modular sWTA networks; and finally, an *implementation* layer composed of distributed neuromorphic hardware such as CMOS VLSI neurons and synapses and their event communication infrastructure.

The method begins by creating the intermediate general-purpose computational layer. The model neurons of this theoretical and therefore precise layer are supported by the relatively imprecise electronic neurons of the implementation layer. These two layers are related by mapping the necessary model neuron parameters onto the circuit bias voltages of the electronic neurons via an automatic procedure in which the circuit biases are calibrated against the model parameters by a series of population activity measurements.

Finally, the high-level behavioral model is embedded in the computational layer by the introduction of sparse connections between sWTA modules so that the overall network gives rise to

attractors that encode the behavioral states of the cognitive model. Additional connections are introduced to provide the necessary transitions between the attractor states (Rutishauser and Douglas 2009). The transitions are conditional on external input. These coupled sWTA networks form a “soft-state machines” which, unlike conventional finite-state machines, combine analog and digital processing in the same circuit.

An example of a task similar to those used in laboratory settings to probe cognition in primates is shown in Fig. 2a. The cognitive neuromorphic agent is challenged with this same task. The agent is implemented using both electronic spiking neural networks and a neuromorphic *silicon retina* sensor that responds to visual patterns displayed on a screen (Fig. 2a) with trains of spikes. The visual scene is composed of independently moving horizontal and vertical bars. Depending on the current context, the neuromorphic agent is required to respond differently to these bars. The context in force is determined by a cue that is transiently shown at the beginning of the experiment and that must be remembered. In the first context the agent must produce response **A** when it observes a horizontal bar entering the right half of the screen; and in the second context it must produce response **B** when it observes a vertical bar entering the left half of the screen. Under all other conditions, the agent should remain silent. The relevance of this task is twofold: It requires processing of real-time dynamic visual stimuli in a state-dependent fashion, and it is comparable in complexity to the tasks used to probe cognition in behavioral studies of humans and animals. The neuromorphic agent was able to perform this task successfully and reliably and produce the correct output by activating the appropriate place-encoded neurons.

The important contribution of this work is that it provides a systematic way to install reliable processing on the underlying unreliable neuromorphic hardware, in a way that simplifies the programming of the desired high-level behavior. This approach is analogous to the software one used to program and compile computational processes in general-purpose digital computers, except that the underlying neuromorphic

Neuromorphic Cognition, Fig. 2 (a) The cognitive task: depending on a contextual cue, certain motions of a horizontal and a vertical bar must be detected. (b–d) Three-level concept for synthesizing the required behavior in an electronic neuromorphic VLSI system. (b) High-level state machine behavioral model that describes the task shown in (a). Filled circles denote states, arrows denote state transitions, and symbols denote input conditions for transition. The asterisk marks the idle state. (c) Computational layer composed of sparsely interconnected sWTA modules, which are configured to express the state machine specified in (b). Each shaded rectangle represents an sWTA module which normalizes the activities of its associated excitatory populations. Colored circles indicate attractor states

established by sparse interconnections (indicated by the *bidirectional arrow*) between the two orthogonal state-holding sWTA modules. Colors conform to states shown in (b). The populations and connections shown in (c) correspond to the “blue” context, indicated by *dashed arrows* in (b). Context cues and direction of motion data are input to the populations (gray circles) of the transition generating sWTA module (large square). The transition sWTA connects to a further output sWTA module. (d) Layout of the analog/digital spiking neural network chip whose voltage and current biases, and routing tables, are automatically configured to implement the computational layer. Rectangles illustrate sWTA neuronal modules

hardware is radically different from digital ones in both system concept and electronic implementation. Because our networks are implemented using spiking neurons and synapses with biologically plausible dynamics, they cast light on how both brains and future neuromorphic technologies could implement cognitive behaviors.

Discussion

So far neuromorphic engineering has succeeded in providing the physical infrastructure for constructing visual and auditory sensors, spiking neural networks, and event-driven effectors that are similar in organization if not in size to the nervous systems of biology. Until now the tasks that these neuromorphic systems have been able to perform are quite simple, so that even the most

sophisticated VLSI systems created were reactive in quality, mapping rather directly sensory percepts to simple actions. Of course, intelligent systems are not simply reactive. Instead, given some knowledge of its environment and its internal state, and some approximate behavioral objectives, an intelligent agent comes to reason that certain combinations of actions are more likely to achieve an objective than others. While we may recognize these properties in the behavior of animals, it has been extraordinarily difficult to evoke them in artificial systems, be they either symbolic or connectionist in design.

Neuromorphic cognition faces the challenge of implementing such properties in real-time behaving sensory-motor systems. This not only requires to identify the organization principles of the brain but also to develop the technology and method for instantiating cognition on physical implementations

of neurons and synapses. Although the neuromorphic neuron and synapse circuits are fabricated using standard CMOS VLSI foundries, they are unlike conventional industrial digital or analog circuits. They are a hybrid of analog and digital asynchronous circuits, and their analog transistors usually run in the subthreshold regime in order to emulate very compactly the crucial functional characteristics of neural systems (Indiveri et al. 2011; Liu et al. 2002). Consequently, neuromorphic circuits are subject to substantial fabrication variability (device mismatch) and operating noise. Unlike digital circuits, analog circuits require dedicated signal restoration mechanisms to avoid signal corruption through successive stages of processing (Sarpeshkar 1998). A similar signal restoration problem holds for biological neurons, as was quickly recognized by von Neumann when he considered alternative architectures for early computers (von Neumann 1958). The sWTA networks described in the previous sections and the neuromorphic circuits that emulate neural dynamics can be used to form signal restoration mechanisms that support reliable computation, even when implemented with imprecise hardware components. Furthermore, given the progress made in spike-based learning and plasticity methods for neuromorphic architectures (Mitra et al. 2009; Pfeiffer et al. 2010; Serrano-Gotarredona et al. 2013) and given the recent developments in methods for synthesizing cognition in neuromorphic systems (Eliasmith et al. 2012; Neftci et al. 2013), the challenge of building bioinspired intelligent agents that can interact with the environment in real time and express cognitive abilities is much more accessible.

Synonyms

Large-scale; Neuromorphic system

Definition

A neuromorphic hardware system is an electronic system for information processing, based, to a certain degree, on the example of the biological nervous system. The operation of the whole system resembles the behavior of a network built from “neurons” and “synapses.” The degree of biological realism varies greatly between different research projects and targeted applications. Large-scale neuromorphic hardware projects target system sizes in the order of at least 10^6 synapses, but some aim for up to 10^{14} . Therefore, scalability is an important aspect of large-scale neuromorphic hardware, which also distinguishes it from medium- and small-scale neuromorphic hardware.

Detailed Description

Since its invention by Carver Mead (Mead 1989) in the 1980s, the term neuromorphic hardware has undergone a big shift in meaning. Was it originally coined for analog circuitry mimicking biological synapses and neurons by maintaining a direct equivalence between membrane currents and voltages in biology and electronics, it is now used for a broad class of microelectronic-based information processing systems built for the purpose of emulating neural systems.

Especially in the field of large-scale neuromorphic systems, a lot of technologies enabling the necessary amount of scalability are adopted from the field of high-performance computing, for example, network protocols and hardware (Moore et al. 2012). In some extreme cases large-scale neuromorphic systems resemble specialized highly parallel computer systems containing no structural elements identifiable as synapses or neurons (Furber and Temple 2007).

What distinguishes all large-scale neuromorphic hardware from high-performance computing systems is that they are purposely built and optimized for the emulation of neural networks. This usually gives them some advantages compared to numerical simulations on traditional computers, like lower energy consumption, faster emulation/simulation speed, and better temporal resolution due to continuous time operation.

Possible disadvantages are lower flexibility, lower precision, more difficult operation, and incompatibility with standard software simulators. Due to the greatly varying circuit techniques used in contemporary large-scale neuromorphic systems, each has its unique set of advantages and disadvantages and needs to be carefully examined for its adequacy for a certain experiment.

The large amount of research invested in the future of high-performance computing has made it obvious that exascale computing will be very expensive, mostly due to its tremendous demand for electrical energy (Kogge et al. 2008). Large-scale neuromorphic computing could be a possible alternative for greatly reducing the energy needed for emulating brain-sized models of biological nervous systems in the near future (Silver et al. 2007).

As stated above, large differences exist in the technical realization of large-scale neuromorphic system, despite being all implemented in contemporary very large-scale integration (VLSI) technology. The most basic distinction is the technical implementation of the neuron emulation. Large-scale neuromorphic systems can be divided in two categories: those using a physical neuron model and those using a numerical neuron model.

Physical Neuron Model

A physical neuron model in a large-scale neuromorphic hardware system is based on an electronic circuit built from metal-oxide-semiconductor field-effect transistors (MOSFET). Arranged around a capacitor that implements the neuron’s membrane capacitance, the circuit emulates the operation of the different ion channels located in the neuron’s cell membrane. By its operation the circuit continuously solves the differential equation for the membrane voltage.

The level of complexity can range from simple leaky integrate-and-fire models (Schemmel et al. 2006) to Hodgkin-Huxley or similar models which are able to replicate complex neuron behaviors like adaptation or bursting (Millner et al. 2010). Also synapses might be either simple current sources or complex conductance-based synapses with built-in short-term plasticity. Although the majority of large-scale neuromorphic systems

implements only point neuron models, some projects have published the first results using multi-compartment neuron models (Indiveri et al. 2011).

In nearly all large-scale neuromorphic hardware implementations based on analog circuits, the action potentials are transmitted as digital signals. Therefore, the neuron acts as analog-to-digital converter, while the synapse resembles a digital-to-analog converter.

To support learning, contemporary large-scale neuromorphic hardware projects usually include some kind of synaptic plasticity, for example, spike timing-dependent plasticity (Markram et al. 2012). Physical neuron models operate in continuous time. The time scale between the electronic circuit and the biological system it models can be different. Existing systems use time scales from 1 to 10^5 , termed “real time” and “(highly) accelerated” models, accordingly. Accelerated systems facilitate the research of long-time behavior of neural systems, like development and learning, as well as statistical and parameter analysis, where a similar network is emulated repeatedly.

Each neuron in the neuromorphic hardware system corresponds to one neuron of the emulated network. Therefore, to scale these systems up, a lot of silicon area is needed. Since the synapses greatly outnumber the neuron circuits, it is important to keep their size as small as possible. For example, a large-scale system with 10^{12} synapses each occupying $100 \mu\text{m}^2$ will need at least 100 m^2 silicon area or approximately 1500 silicon wafers with 30 cm diameter.

Most physical model-based large-scale neuromorphic systems store the synaptic strength in static memory (SRAM) in close vicinity or directly within the synapse circuits. Large research effort is currently invested to reduce the area associated with this storage by using resistive or floating gate memory circuits instead (Adhikari et al. 2012).

Numerical Neuron Model

In large-scale neuromorphic hardware based on numerical neuron models, a digital circuit calculates the membrane voltage, which is represented

by a binary number. It implements a numerical integration algorithm to solve the differential equations of the model. Since this numerical model has no relation to the biological real time, its operation can be synchronized to the whole network model in any suitable way. For example, one neuron circuit can be multiplexed to calculate the membrane voltages of a whole population of emulated neurons. By using industry standard dynamic memory (DRAM), a neuromorphic hardware based on numerical neuron models can emulate much larger synapse numbers than its counterpart based on physical neuron models, but at the cost of an equally higher energy consumption.

The architecture ranges from fixed-function integrator circuits implementing a certain neuron model like integrate-and-fire (Merolla et al. 2011) to systems based on full-blown microprocessor cores capable of running arbitrary complex models, limited only by memory capacity and processing speed.

System Level

On a higher level, any large-scale neuromorphic hardware implements some kind of high-bandwidth programmable interconnect system which allows the replication of the emulated network’s topology within the neuromorphic system. According to the continuous time operation of large parts of their system, the communication protocol used in such an interconnect system is usually a simple fire-and-forget type of protocol, carrying the destination neuron address as its sole payload. Handshake-based systems like the original address event representation (AER) scheme are not usually employed in large-scale system, due to the round-trip delay associated with the handshake signals.

To cope with the varying bandwidth demand of a neural network, where short high-activity bursting phases might be intermixed with long quiet periods, a high level of over-provisioning of communication bandwidth is employed. To alleviate the cost associated with such over-provisioning, the power consumption of the interconnect

hardware must be strongly correlated to the data rate (Schemmel et al. 2010).

Some implementations also digitize the time of the neural events, which allows them to better equalize the available bandwidth. In addition to the destination address, an event packet in this case also contains a time-stamp field, storing the time the event has to arrive at its destination. A network based on time-stamped event packets can be easily extended to implement the delays of the emulated network by adding the delay value to the time-stamp field.

Definition

The biological cochlea is a bony, fluid-filled structure in the inner ear. It performs the transduction between the pressure signal representing the

acoustic input and the neural signals that carry information to the brain. The cochlea is spiraled from the base to the apex, containing approximately 2.5 turns. The internal part of the cochlea is divided into three chambers (scalae): scala vestibuli, scala media, and scala tympani; Reissner's membrane separates the first chamber from the second chamber, and the basilar membrane (**BM**) separates the second and third chambers. A specialized structure, the organ of Corti, sits atop the basilar membrane. It contains both the inner and outer hair cells (**IHCs** and **OHCs**, respectively). The tips of these cells have hairlike structures, called stereocilia. Deflections in the stereocilia of the IHCs generate neural signals that travel to the brain. Neural signals from the brain can alter the length and width of the OHC cell bodies, affecting the mechanical properties of the BM, and thus its response to sound vibrations.

Airborne sound enters the ear via the ear canal and vibrates the eardrum, which in turn causes vibration of the three middle ear bones, one of which causes the cochlear fluid to vibrate. These small bones perform impedance transformation through a leveraging action, so that airborne sound can be transmitted into the fluid-filled cochlea.

At the base of the cochlea, the physical characteristics of the BM (it is narrower and stiffer) are such that it responds with greater movement to high frequency stimuli, whereas at the apex, the BM is wider and more flexible, so that it responds better to low frequency stimuli. Each position along the BM can thus be assigned a characteristic frequency that produces the greatest deflection at that place.

When the BM moves, the organ of Corti is displaced. The stereocilia of the IHCs are then displaced by the viscous drag of the cochlear fluid, making the displacement of the IHC's stereocilia proportional to the velocity of the basilar membrane motion. This movement of the stereocilia causes a change in membrane potential within the IHC, which in turn causes the release of neurotransmitter from the IHC. This release causes spiking activity in neurons, the spiral ganglion cells, whose axons make up the auditory nerve.

The stereocilia of the OHCs are attached to another structure, the tectorial membrane, and they are thus displaced due to the shear between the rigid upper surface of the organ of Corti and

the tectorial membrane. The OHCs change their length as a function of their membrane potential and provide active undamping of the mechanical structure. This allows the selectivity of the cochlear filters to adapt as a function of the intensity of the input sound.

Detailed Description

Biological cochleas use a space-to-rate encoding in which the input sound is encoded as trains of pulses created from the outputs of a set of broadly frequency-selective channels (Shamma 1985). The pulses are phase locked for low frequencies, and this phase locking disappears for frequencies above around 3 kHz (Palmer and Russell 1986). Encoding the information this way allows sparser sampling of frequency information according to the active frequency channels rather than the maximal sampling rate required to capture all information from a single audio source.

Silicon cochleas have been developed for over 20 years starting with the work of Lyon and Mead (1988). These designs model the biophysics of the BM as a large number of coupled filter stages. The architecture of the silicon cochlea varies from the cascaded architectures (Watts et al. 1992; Sarpeshkar et al. 1998; van Schaik et al. 1996) first introduced by Lyon and Mead (1988), modeling the phenomenological output of the cochlea, to a resistively coupled bank of band-pass filters (Watts et al. 1992; Wen and Boahen 2006; Fragniere 2005; Hamilton et al. 2008) modeling the role of the BM and the cochlear fluid more explicitly (Fig. 1). The cascaded architecture is preferred over the coupled band-pass architecture for better matching, ease of implementation, and a sharp high frequency roll-off of the filters.

The IHCs have been modeled as half-wave rectifiers (**HWRs**) along with possible models of automatic gain control of outer hair cells (Hamilton et al. 2008; Wen and Boahen 2009; Katsiamis et al. 2009). Recent cochleas also include circuits that model the role of spiral ganglion cells by asynchronous output quantization in the time domain with transmitted data encoded using the address-event representation (**AER**) (Wen and Boahen 2009; Lazzaro et al. 1993;

Neuromorphic Sensors, Cochlea,

Kumar et al. 1998; Sarpeshkar et al. 2005; Georgiou and Toumazou 2005; Abdalla and Horiuchi 2005; Chan et al. 2007; Liu and Delbruck 2010; Liu et al. 2010a).

set by the amplitude and frequency of the input and the amount of charge needed to generate an event.

Filter Channel Circuits

Each stage of the filter bank usually consists of a second order section (SOS) filter in the case of the cascaded architecture. The characteristic frequencies of the filters along the cascade vary logarithmically with position similar to the approximate logarithmic dependence of the preferred frequency selectivity with position along the basilar membrane of the biological cochlea.

Each SOS consists of two forward filters, made from a transconductance amplifier and a capacitor, and one feedback transconductance amplifier. The difference of the outputs of the forward filters within a single SOS is the input to the subsequent IHC circuit. This difference readout adds a desirable zero to the transfer function without introducing undesirable gain proportional to frequency, as would occur with a temporal high-pass filter (van Schaik et al. 1996). It sharpens the filter response to approximate closer a band-pass response and reduces the phase accumulation across the cascade.

A half-wave rectification circuit implementing the IHC is a simplified model of the response of the IHCs of the biological cochlea. The circuit output drives spiral ganglion cell (SGC) circuits, each implemented as an integrate-and-fire neuron model. The number of events created in a cycle is

Event Data from Cochlea

Figure 2 shows the SGC outputs (AER events) and the analog input sound waveform from the latest binaural cochlear system with 64 channels, called the AEREAR2. The outputs are in response to a spoken sentence at a distance of 1 m from the system at normal speech volume (65 dB LAF SPL as measured with a Bruel & Kjaer 2250).

The AEREAR2 system implements a model of the BM, the IHC, and multiple SGCs with different thresholds driven by each IHC. It is the first fully integrated system that combines features of previous silicon cochlea designs that are robust to mismatch, along with novel features for easier programmability of the architecture and operating parameters. The chip includes integrated microphone preamplifiers (Baker and Sarpeshkar 2003), local gain adjustment, and on-chip digitally controlled biases (Delbruck and Lichtsteiner 2006). The individual basilar membrane and SGC circuit signals can also be digitized and read into the computer through the USB port. It has open-sourced host software APIs and algorithms which enable rapid development of application scenarios (Delbruck 2007). A bus-powered USB board enables easy interfacing of the AEREAR2 to standard PCs for control and processing.

The time-stamped AER events with a 1 ms resolution are sent to a PC where they are processed

Neuromorphic Sensors, Cochlea, Fig. 2 Response to spoken sentence “The shadow vanished.” (a) Events or SGC outputs from the 64 channels of one ear of the binaural AEREAR2. (b) Sampled audio from right

microphone preamplifier output. Low channels correspond to high frequencies and high channels to low frequencies. Best characteristic frequencies range from 100 Hz to 20 kHz

for applications. For natural sounds, off-chip microphone preamplifiers (MAX9814) with 20 dB range of automatic gain control or on-chip microphone preamplifiers with an 18 dB range of digitally controllable gain can be used. Input can also be applied from a PC sound card directly to the filter cascade (i.e., bypassing the preamplifiers).

In Fig. 2a, the dots represent events recorded from the AEREAR2 in response to a spoken sentence. Some channels are more excitable than others and have background activity leading to a sustained background event rate of about 4 keps. The average event rate is 80 keps and the peak event rate is around 325 keps. The sampled microphone output recorded using the onboard ADC is displayed in Fig. 2b.

Applications

Various cochlea implementations including the binaural AEREAR2 have been used for various

auditory tasks including spatial audition (Chan et al. 2007, 2010; Abdalla and Horiuchi 2008; Finger and Liu 2011). Processing is done on the asynchronous spike events rather than on spectrograms generated from sampled raw audio inputs. Post-processing can be cheaper because only a sparse stream of events needs to be processed. This event-based system is being tested for other auditory tasks such as speaker identification (Chakrabartty and Liu 2010; Liu et al. 2010b, 2012; Abdollahi and Liu 2011) and multi-sensor fusion.

Neuromorphic Sensors, Head Direction

T. K. Horiuchi¹ and T. M. Massoud²

¹University of Maryland, College Park, MD, USA

²Department of Electrical and Computer Engineering, University of Maryland, College Park, MD, USA

Definition

A neuromorphic VLSI head-direction system is a physical circuit (VLSI) model of the head-direction cell system found in the mammalian brain used to maintain and update a compass-like estimate of the animal's orientation in the environment. Currently, the physical circuit implementations are constructed in mixed-mode (analog and asynchronous digital) VLSI circuits that model spiking neural networks.

Detailed Description

A head-direction cell (described in mammals) is a type of neuron that has been found to become active when an animal is oriented in a particular direction with respect to the environment (Taube et al. 1990a; Sharp et al. 2001). With different neurons responding to different directions, the head-direction cell *system* is thought to reflect the animal's estimate of its orientation in the environment with respect to some reference orientation. While individual neurons maintain their orientation preference to each other in different environments, the system's overall reference orientation varies with the environment. The reference orientation appears to be linked to sensory cues (e.g., visual landmarks), and the activity is updated by vestibular and other self-motion signals. Head-direction cells have been found in many different areas of the hippocampal formation (hippocampus, entorhinal cortex, post-subiculum, etc.) linking their activity to spatial navigation (O'Keefe and Dostrovsky 1971; Hafting et al. 2005; Taube et al. 1990a; Moser et al. 2008) and memory tasks. More than a read-out of orientation, it is believed that the system of neurons operates collectively as an integrator of angular velocity (i.e., a "ring integrator"), converting vestibular signals (or other sensory- or memory-based information) into changes of orientation (Sharp et al. 2001; Taube 2001; Stackman and Taube 1997; Taube and Bassett 2003) and actively maintaining this estimate, even when sensory information is unavailable.

The ring-integrator model of the system consists of neurons or neuron groups connected in a ring. One and only one "location" on the ring should be active at a time, indicating the current estimate of orientation with respect to a reference angle. To operate as an integrator of angular velocity (which is available from the vestibular and visual systems), the neural activity in the ring should be self-sustaining and should move around the ring with a velocity proportional to the angular velocity of the animal. In modeling the head-direction system, the basic ring model is widely used; however, the mechanisms for movement of the activity on the ring vary significantly (e.g.,

Skaggs et al. 1995; Zhang 1996; Xie et al. 2002; Redish et al. 1996; Goodridge and Touretzky 2000). Only recently have spiking neurons and more detailed network connections been used to simulate these systems (Song and Wang 2005; Degris et al. 2004; Stratton et al. 2009).

VLSI Models

In the neuromorphic VLSI field, several different spiking neuron ring "oscillators" have been described that could function as a head-direction cell system; however, the ability or intention to variably control the speed and direction of the activity around the ring was always very limited (e.g., Wolpert 1996; Chicca et al. 2004; Sridharan et al. 2008). The work by Massoud and Horiuchi (2011a) addresses the speed control issue directly and is described below. A key limitation in the development of all of these neural models of the head-direction system has been the lack of information about the biological network interconnections that define the computation. To our knowledge, there has only been one explicit effort to model the head-direction system in VLSI-based spiking neurons (Massoud and Horiuchi 2011a).

In this work, a population of spiking VLSI neurons (representing the head-direction cells) is connected in a ring architecture (Fig. 1). Neighboring neurons up to seven neurons away are interconnected via recurrent synaptic connections with local excitation and surround inhibition. This center-surround recurrent projection is designed to produce self-sustaining spiking activity and promotes an active group size that is approximately the same size as the excitatory region of the connectivity kernel. There is a global inhibitory neuron (spiking) that receives excitation from all locations on the ring that projects inhibition back onto the ring uniformly to form a "winner-take-all" function, allowing only one location on the ring to be active at one time. Many variations of this center-surround feedback structure in neuromorphic VLSI with spiking neurons can be found throughout the literature (e.g., Indiveri et al. 2001; Chicca et al. 2004; Merolla and Boahen 2006). These neurons and connections satisfy

the need to produce a self-sustaining estimate of orientation and to allow the representation of only one orientation at a time.

To move this “bump” (i.e., “group”) of activity around the ring in response to angular velocity, three additional movement-related neurons are associated with each location on the ring (Fig. 2). The additional neurons are labeled “disinhibition,” “left rotation,” and “right rotation.” To drive the rotation system, two input signals are used: “leftward speed” and “rightward speed.” These two speed-indicating inputs project

globally to their corresponding rotation neurons and fire spikes at a rate proportional to the leftward and rightward rotation speeds of the animal and do not fire spikes in the non-preferred direction. The left rotation neuron at each location projects excitation one step to the left, and the right rotation neuron projects excitation one step to the right. To prevent these rotation neurons from indiscriminately activating neurons throughout the ring, the disinhibition neurons (which are tonically active) suppress the rotation neurons at all locations *except* where the bump of activity

Neuromorphic Sensors, Head Direction, Fig. 1 A ring of neurons (*left*) each with local and global connections. A limited version of the local connections of one neuron is shown for clarity. The neuron in the center of the ring (*shaded gray*) is the global inhibitory neuron. This feedback inhibition allows only one group of neurons (“bump”)

to be active at a time (*shaded in black*). The global inhibitory neuron normalizes the total network activity through inhibitory feedback. Additional neurons and connectivity for moving the bump activity (discussed below) are not shown. (From Massoud and Horiuchi 2011a)

Neuromorphic Sensors, Head Direction, Fig. 2 *Left:* Connectivity diagram of the bump movement neurons. The arrow head indicates an excitatory connection, and the circle-shaped head indicates an inhibitory connection.

The network connections that maintain bump activity (see Fig. 1) are not repeated here for clarity. (From Massoud and Horiuchi 2011a). *Right:* Neuromorphic VLSI implementation of the system

is. The active head-direction cells of the bump inhibit the disinhibition neurons, allowing the rotation neurons to cause a shift in the bump location. By disinhibiting the rotation neurons, the angular velocity signal is able to drive the rotation neurons at a rate proportional to the input. In this system, when disinhibited, these neurons are configured to faithfully transmit one output spike for each input spike.

While this spike-based neural network has been demonstrated in a “mean-rate” mode (i.e., firing rate approximating a continuous variable) where the spiking rates are higher and the time constants are longer, the use of the more pulsatile mode of spiking neurons (i.e., lower firing rates and short time constants) creates some interesting phenomena that can be useful to the operation of the system (Fig. 3). In the recurrent connections that create the bump profile, local excitation can produce a synchronizing and rate-discretizing effect when the neuron with the largest input fires first, sending a pulse of excitation to its neighbors. If a neighboring neuron is then driven to spike, it will trigger another excitation pulse locally, entraining more local neurons. Both the surround inhibition and the global inhibitory neuron will limit the growth of this process. Within the “winning group” of neurons, although each neuron may receive different levels of input,

they will each fire a spike (with different latencies) whenever the leading neuron fires a spike first. The entire winning group will tend to fire at the rate of the fastest neuron and in temporally staggered order, but the group firing will appear roughly synchronous. The choice of synaptic weight and time constant will modulate the degree to which this synchronous firing occurs.

A second phenomenon associated with the spiking representation is the reduction in position drift of the activity bump due to fabrication mismatch in the transistors. When a winning group is firing stably, it actively suppresses its neighbors via lateral connections and the global inhibitory neuron. Because this spike-triggered inhibition occurs right after the winning group fires, increasing the gain of the inhibition increases suppression of the nonwinners, but very weakly reduces the firing rate of the winning neurons. Similar observations have been made in other VLSI systems (e.g., Sridharan et al. 2010; Giulioni et al. 2011). For this reason, it is possible to tune the parameters such that a significant additional input to the neighbors is required to shift the pattern left or right. When the system is operated with less pulsatile currents, the bump pattern becomes prone to drifting around the ring and into local minima (locally favored positions) created by transistor fabrication mismatch.

Neuromorphic Sensors, Head Direction, Fig. 3 *Left:* Demonstration of the movement of the activity bump around the ring in both directions with variable rotation speed. *Right:* Plot of the average bump velocity on the ring

(in neurons/sec) as a function of the rotation input signal (spikes/sec). The vertical bars represent one standard deviation from the average. (From Massoud and Horiuchi 2011a)

Discussion: Related Work in the HD System and Related Neural Systems

In addition to the head-direction cell system described above, Massoud and Horiuchi (2011b) have used the HD system (in a hybrid software/hardware system) to demonstrate how the short-term memory of objects sensed in different directions can be used to correct the integrator for velocity integration errors.

With more neuromorphic VLSI researchers entering the field and a strong interest in the computational neuroscience community to model the hippocampal formation and navigation-related areas, more VLSI models are certain to emerge, particularly as their potential for guiding micro-aerial vehicles increases.

Definition

Neuromorphic olfaction is an emergent field of research which aims at unraveling computational principles of biological olfactory systems and translating them into algorithms and devices. The resulting technology has high potential for a wide range of practical applications (detection of chemical species, diagnosis, crime prevention and security, etc.) as well as a tool for basic research to verify hypotheses about the sense of smell in biological systems. Neuromorphic olfactory systems are composed of a sensing part which provides selective responses to particular chemical as input to a biologically inspired computational stage.

Detailed Description

Most animals rely on smell as sensory modality for survival and reproduction: it allows them to

detect predator, food, and mates. The biological olfactory system is an ideal model for the study of information processing in biological neural networks. Furthermore, knowledge about animal olfaction could be used to improve performances of artificial olfactory systems. The technology for artificial smell is still in the early stages of developments, but it has a wide range of possible applications ranging from quality control in food industry and detection of harmful substances (e.g., bacteria, drugs, explosives, etc.) for crime prevention and security to diagnosis in medicine.

Neuromorphic olfaction aims at understanding the computational properties of the sense of smell in biological systems and building artificial systems operating on similar principles and based on neuromorphic VLSI circuits. The challenges in neuromorphic are twofold: On the one hand, chemosensors need to be developed that match their biological counterparts in performance. On the other hand, algorithms and computing substrates are needed to analyze sensor data to quickly arrive at a detection and accurate identification of the odor stimulus. In the following, we give an overview on chemosensor technology, including biohybrid systems, and on neuromorphic implementations of algorithms for scent detection and identification.

Chemosensor Technology

Strictly speaking, there exist no neuromorphic chemosensors in the sense that the technology mimics the neuronal principle used by biological olfactory neurons. The majority of today's chemosensors operation is based on the measurement of the resistance of a sensing material that is exposed to vapor. The mechanism that causes the resistance change varies with sensor technology. Another recent approach are biohybrid sensors. In biohybrid sensors, the actual chemosensing step is performed by biological sensors, like isolated olfactory receptors, genetically engineered cells expressing the receptors, or preparations of olfactory tissue. The biological response is read out with an electronic circuit.

Most approaches have in common that the identity of the volatile (or solute chemical) is derived from the combinatorial activity of a sensor array, much like the olfactory system evaluates the combinatorial activity pattern of the diverse olfactory receptors in the nose. Each individual sensor has a specific response spectrum. These response spectra are typically rather broad, i.e., the sensor responds to a wide range of odorants. Hence, odor spectra usually overlap considerably between sensors. At the expense of a reduced coding space compared to nonoverlapping spectra, overlapping odor spectra enable partial redundancy in odor representation, which may be used to increase signal-to-noise ratio or the robustness against receptor dropouts.

Electronic Chemosensors

Three major classes of chemosensor can be distinguished according to their basic mode of operation: polymer and metal oxide (MOX) sensors, optical chemosensors, and piezoelectric sensors. A detailed description of electronic chemosensor technology is beyond the scope of this entry; we will only provide a concise overview on the available technologies. An in-depth review with references to original literature is provided by Arshak et al. (2004).

In polymer sensors and MOX sensors, the vapor is absorbed by the sensing material, interacts with it, and generates a change in the resistance of the material. This resistance change can be measured, and it acts as the output signal of the sensor. The sensor's selectivity to odorants is influenced by the composition of the sensing material, that is, the polymer components, or the metal alloy in MOX sensors. In addition, the sensors can be coated with thin films to change their selectivity. Varying the thickness and material of the film provides an additional possibility to influence sensor selectivity. MOX sensors require high temperatures to operate (150–500 °C), and ligand selectivity changes with temperature. Hence, the same sensors will provide different selectivity at different temperatures. This

circumstance can be exploited to create a sensor array with diverse characteristics from one single sensor material, by arranging a number of identical sensors next to each other and creating a temperature gradient. Polymer and MOX sensors are relatively cheap to build. The rich choice of commercially available materials enables the design of sensors with diverse characteristics. Both sensor types have fast response and recovery times. On the downside, polymer and MOX sensors are sensitive to changes in relative humidity. Hence, humidity must either be controlled or calibrated for when working with those sensors. MOX sensors have high power consumption due to the heating element that is required for their operation.

Optical chemosensors consist of fibers that are coated with fluorescent material. Upon interaction with volatiles, this material changes its fluorescent properties, e.g., spectrum, intensity, or wavelength of the fluorescence. This fluorescence is measured and converted into a voltage output signal. Optical chemosensors are immune to electromagnetic interference and fit a small and light package. As a disadvantage, this approach requires complex circuitry to measure the fluorescence change. In addition, fluorescent dyes are susceptible to bleaching due to light exposure and decay with time.

Piezoelectric sensors indirectly measure the mass of absorbed volatiles. Two kinds of piezoelectric sensors can be distinguished: surface-acoustic wave (SAW) sensors and lever-based sensors. In SAW sensors, a SAW with a frequency around 400 MHz is created on the sensing material. This frequency changes when molecules are absorbed. The exact amount of frequency change depends on the mass of the absorbed molecules. In lever-based sensors, a small lever that is coated with odor-absorbing material is attached to an electrode. The resonant vibration frequency of this lever changes with odor absorption and can be measured. Using different coatings, these sensors can be tuned to a wide variety of odors. They provide high sensitivity and respond quickly. On the downside, they require complex circuitry to measure frequency changes.

Biohybrid Systems

By definition, biohybrid approaches employ biological sensors for chemical sensing, like biological receptors, tissue, or even the entire animals. Animals have been used for centuries to enhance and complement human olfactory sensing, e.g., as in using dogs for scent tracking, and “whole-animal biosensors” are actually used in practice (see Persaud (2012) for a review). Cell-based biosensors exploit cellular responses to chemical and other external stimulation to detect a wide range of environmental cues (Persaud 2012).

Another approach is to couple biological olfactory receptors (ORs) and other chemosensitive proteins or other olfactory proteins with an electronic readout (reviewed in Persaud (2012) and in more detail Du et al. (2012)). This approach faces two major challenges: First, olfactory receptors or other olfactory peptides must be extracted or synthesized in sufficiently pure form. Second, these probes must be immobilized on a transducer in order to achieve reliable coupling with the electronic readout.

Four principal methods are available to produce receptors for OR-based biosensors: extraction from biological tissue or cells, cell-based expression of ORs using genetic methods, cell-free expression using the expression machinery *in vitro*, and chemical synthesis (for olfactory peptides). Extraction from living tissue is convenient because the natural protein structure and connections to transduction machinery in the cell are maintained. On the downside, extraction of specific ORs is inefficient. Hence, it is difficult to achieve specific ligand selectivity with this approach. Moreover, as the extracted ORs retain some cellular components, they must be provided with a culturing environment, much like natural cells, which presents a major challenge to the applicability of e-noses with extracted ORs. Obviously, this is difficult to achieve in commercial e-nose approaches.

Heterologous expression of ORs abolishes some of these disadvantages. Using well-established expression systems in human embryonic kidney (HEK) and yeast cells, the production of specific ORs is feasible (reviewed in Du et al.

(2012)). As in the extraction approach described above, the ORs retain their location in the membrane. In addition, through manipulation of the amino acid sequence of the OR protein, it is possible to furnish the OR proteins with cellular tags that facilitate their immobilization on the sensor substrate. On the other hand, expression systems are not very efficient due to the relatively low throughput of protein synthesis (Hamana et al. 2010).

Cell-free protein synthesis is a promising tool to enable cost-efficient OR production with high throughput. Protein synthesis is performed by adding DNA or mRNA and the other components required for protein synthesis (e.g., amino acids, nucleotides, ATP) to the cellular protein synthesis machinery *in vitro* (Katzen et al. 2005). Kaiser et al. (2008) report successful production of the human variant of the I7 receptor and its usage in a biosensor (Kaiser et al. 2008).

The highest abstraction from biological OR production is provided by direct chemical synthesis of OR-based biosensors, as reported by Sankaran et al. (2011a, b). First, odorant-binding domains are heuristically determined from the OR sequence, using computational modeling to predict the binding selectivity. Then, a polypeptide is designed from the amino acid residues involved in odorant binding in LUSH, an odorant-binding protein in *Drosophila*. This polypeptide is synthesized and used as a biosensor. This approach is particularly efficient due to the fact that only comparably short polypeptides are produced instead of the entire ORs and their transduction machinery. Moreover, there are many possibilities to design polypeptides in order to produce sensor peptide collections with diverse ligand selectivity.

In order to use OR vesicles or OR-derived peptides in biosensors, they must be immobilized on a transducing electrode. The most straightforward method for immobilization is to coat the electrode with a suspension of ORs. This method has been widely applied and the parameters for immobilization have been investigated (see Du et al. (2012) for references). A more complicated, but also more specific, approach is provided by immobilizing ORs using a self-assembled multi-layer strategy. In this approach, OR-specific

antibodies bound to the electrode using compound peptides, as reported by Hou et al. (2006). The specificity of the antibodies allows for directed immobilization of the desired OR to a specific location on the transducer. The olfactory peptides developed by Sankaran et al. (2011a, b) have been immobilized by direct covalent binding to the electrode, enabled through an AU-S chemical bond.

Taken together, biohybrid sensors address many of the shortcomings of purely electronic sensors, for example, ligand selectivity and response time. However, practical implementations of such devices are yet to be developed, as the technology to produce biological receptors and fixate them on electrode substrates evolves.

Neuromorphic Implementations

To our knowledge, the first truly neuromorphic olfaction device was proposed in 2007 by Koickal et al. (2007). The authors presented a fully integrated neuromorphic olfaction chip comprising a chemosensor array, a signal conditioning circuitry, and a spiking neural architecture with on-chip spike time-dependent plasticity (Markram et al. 1997). The very-large-scale integration (VLSI) device was fabricated using Austria Micro Systems (AMS) 0.6 μm CMOS process. Odor-sensitive material (carbon black composite) was deposited in post-processing. The device contains different sensor types to react to different chemicals. The signals produced by the chemosensor array were preprocessed for DC signal cancellation and constituted the input for the first layer of a spiking neural network. Hence, they can be considered the equivalent of olfactory receptor neurons (ORNs). A second layer modeled the projection neuron (PN). Each PN integrated inputs from several ORNs and produced the output of the olfaction device. Lateral inhibition in the PN layer enhanced selectivity of the neuronal response. The complete system was integrated in a single chip. On-chip test results demonstrated the functionality of all components as well as the signal path through the entire neuromorphic device. System circuit simulation

results were described to evaluate network performances. A further prototype chip was designed and testing and evaluation of this device was mentioned as future work. Unfortunately, there was no follow-up of this promising system by the authors, who continued this line of research using conventional digital hardware (Pearce et al. 2013). More in general, neuromorphic implementation of olfactory devices were not reported in the literature for some years and only recently the research community has shown renovated interest in this field (Beyeler et al. 2010; Ng et al. 2011; Hsieh and Tang 2012; Imam et al. 2012; Pfeil et al. 2013).

A hardware model of the antennal lobe (AL) of the fruit fly *Drosophila melanogaster* was described in Beyeler et al. (2010). Unlike in the above-described publication, the focus here was not on odor classification but rather on simulation of the biological system and the transformation of odor representation. The authors presented the results of a linear simulation, a spiking simulation with integrate-and-fire (IF) neurons, and a real-time hardware emulation using neuromorphic VLSI chips. They used an input data set of neurophysiological recordings from ORNs of *Drosophila* and studied the role of global feedforward inhibition. The results demonstrated that inhibition could be used by the AL to increase angles between odor pairs and therefore improve odor discriminability.

The gas recognition device proposed by Ng et al. (2011) offers an interesting solution to gas identity coding: 2D spatiotemporal patterns of spikes are generated in response to gas exposure. Gas identification is performed through match with a reference gas stored in a library of 2D spatiotemporal signatures. Spatiotemporal signatures are concentration invariant and unique for each gas. Gas concentration is encoded in the latency of the spikes. Classification performances are evaluated with three gases and 94.9% correct detection rate is achieved.

A complementary approach was proposed in 2012 by Hsieh and Tang (2012). They described a VLSI implementation of a spiking neural network inspired by the rodent olfactory bulb. A single chip can be trained to produce mean frequency

encoding of up to three gases or odor categories. Classifying more than three odors requires multi-chip systems (not presented in the paper). Classification performance was evaluated with three gases using odor data sampled by a commercial e-nose (Cyrano329). The system achieved 87.59% correct detection rate.

A hardware model of the glomerular layer of the mammalian olfactory bulb was recently described in Imam et al. (2012). As in Beyeler et al. (2010), the authors focus on detailed simulation of the biological system and study the transformation of odor representation in the olfactory bulb. The authors show that the implemented network improves the signal-to-noise ratio of odor representation and generates sharply tuned responses which are normalized with respect to the global activity. To perform odor classification, the output representation should be further processed by any pattern recognition system. Unfortunately, no quantitative data is shown to evaluate network performances in terms of odor separability (as compared to the input representation). Nevertheless, this model is not only an important step toward biomimetic neuromorphic olfaction systems but also a useful testbed to evaluate hypotheses on olfactory coding in spiking networks.

Another recent study implemented an olfaction-inspired network on a mixed-signal neuromorphic platform that reduces the receptive field overlap through lateral inhibition (Pfeil et al. (2013), section “Insect Antennal Lobe Model”). It is a neuromorphic implementation of an earlier approach to olfaction-inspired processing and classification of multivariate data (Schmuker and Schneider 2007). In contrast to the work by Imam et al., the focus of Schmuker and Schneider (2007) was on the classification of odors with a network that adapts the architecture of the insect olfactory system, but without claiming to reproduce the biological template in the closest detail. It consisted of a three-layer architecture, mimicking (1) ORN, (2) PN and lateral inhibition, and (3) a naive Bayes classifier that modeled higher brain areas which assign a certain odor quality to the input vector of ORN activities. The recent study

by Schmuker et al. (2014) implemented and applied a neural network on neuromorphic hardware for the classification of generic multivariate data sets. The network model is directly inspired by the olfactory system of insects and builds upon earlier work. It combines (1) a virtual receptor approach to convert any real data into ORN spike trains, (2) a decorrelation layer with glomerular structure and lateral inhibition, and (3) plastic synapses from the PNs onto distinct pools of association neurons (ANs) where each pool represents a single data class. Reward-based learning in the training phase optimizes the weights between PNs and ANs. In the test situation the network performed on par with the naive Bayes classifier on a number of different data sets including e.g. the well-known MNIST data set of handwritten digits.

Table 1 summarizes the published studies neuromorphic implementations of olfactory circuits.

Future Directions for Research

The development of effective neuromorphic olfactory systems is hindered by open challenges at the level of the sensors as well as the computational part. Depending on the technology used, gas sensors still deal with problems like sensor degradation, trial-to-trial variability, poor selectivity, or comparably low signal-to-noise ratios, requiring the signal to be averaged over long exposure times in order to arrive at reliable scent identification. Biohybrid approaches address many of these issues but require unconventional technology which makes it difficult to fabricate them in large quantities.

Sensor variability and poor chemosensor selectivity are also common in the biological system and might be tackled in the computational stage of neuromorphic olfactory systems. Evolution found good solutions for discriminating behavioral relevant odors despite the limitations of the sensory front end. Researchers working in the field of neuromorphic olfaction should tightly cooperate with biologist and modelers to advance the

Definition

Neuromorphic sensors are artificial man-made sensors that try to imitate some of the working principles or structures of their biological counterparts. A neuromorphic vision sensor is,

therefore, an artificial man-made vision sensor that mimics some of the working principles or structures found in living animals' visual systems.

Detailed Description

Conventional video cameras are based capturing a sequence of still frames. Improving a camera means normally to increase the total number of pixels (resolution) and/or to increase the number of frames per second that can be captured, while reducing sensor area, power consumption, and possibly fabrication cost. These cameras just capture the light intensities of visual reality. If they are to be used in an artificial vision system (e.g., for robotics), then subsequent computing resources need to be allocated to analyze the sequence of captured frames and extract relevant information for decision making. The more resolution or the higher frame rate a camera has, the more computing power is required for performing artificial vision.

In the biological domain, biological retinæ do not capture sequences of still frames. Biological retinæ include sophisticated focal-plane processing circuitry that performs powerful signal preprocessing on the pixel-level light intensities, before sending visual information to the visual cortex in the brain.

A wide variety of neuromorphic vision sensors have been reported by researchers, including simple luminance to frequency transformation sensors (Culurciello et al. 2003), time-to-first spike coding sensors (Ruedi et al. 2003; Chen and Bermak 2007), foveated sensors (Azadmehr et al. 2005), temporal contrast vision sensors (Lichtsteiner et al. 2008; Posch et al. 2011; Serrano-Gotarredona and Linares-Barranco 2013), motion sensing and computation systems (Ozalevli and Higgins 2005), and spatial contrast sensors (Boahen and Andreou 1992; Ruedi et al. 2003; Costas-Santos et al. 2007; Leñero-Bardallo et al. 2010), to mention just a few. Here we will briefly describe only three such focal-plane preprocessing computations and explain very simplistically how the computations can be

performed using dedicated chip circuitry resulting in compact retina chips. These focal-plane computations are as follows: (1) spatiotemporal light average, (2) spatial contrast, and (3) temporal contrast.

Spatiotemporal Light Average

One of the first focal-plane neuromorphic computations reported was obtaining a spatiotemporal average of luminance, covering a certain spatial range and temporal range. This can be done by using a diffusive grid, as shown in Fig. 1. Each node i in the grid represents a pixel and contains a photo diode and a capacitor. The grid includes resistive (diffusive) interconnections among neighboring pixels, which can be made using resistors or transistors (Mead 1989; Liu et al. 2002). This way, if there is a gradient in pixel photo current I_{phi} levels for a given pixel neighborhood, it will translate into a gradient in pixel voltages V_i , thus producing “diffusive currents” flowing through the diffuser elements from pixel to pixel, trying to compensate the photo current (light) gradient. The result is that the voltage profile formed at the pixel nodes will be a smoothed version of the original light profile, and each pixel

voltage represents an average over a given local spatial region. The effect of the capacitor at each pixel is to introduce an additional temporal average for the case photo currents that are changing in time. This spatiotemporal average pixel voltage representation can be translated, for each pixel, into a current I_{avgi} , using some circuit element (represented by a gray diamond in Fig. 1).

Spatial Contrast Computation

Using the spatiotemporal average current I_{avgi} together with a replica of the pixel photo current I_{phi} in a “current ratio computing circuit” and subtracting a reference (unity in this case), one obtains a representation of spatial contrast:

$$I_{conti} = \frac{I_{phi}}{I_{avgi}} - 1 = \frac{I_{phi} - I_{avgi}}{I_{avgi}}$$

Figure 2 illustrates a pixel signal profile through a one-dimensional section where the photo current profile shows a step, the average light profile is a smoothed version of this step, and the spatial contrast is a normalized light-level-independent profile highlighting the regions with changes of light.

Neuromorphic Sensors, Vision, Fig. 1 Schematic illustration of diffusive grid for spatiotemporal pixel-neighborhood average computation

Temporal Contrast Computation

Temporal contrast is the relative variation of light over time at a single pixel. Therefore, no inter-pixel interaction is required. Figure 3 illustrates a possible pixel diagram for computing temporal contrast at the focal plane. Pixel photo current I_{phi} is transformed into a log voltage $V_{logi} = V_o \log(I_{phi}/I_o)$, where V_o and I_o are constants. This voltage is fed into a voltage differencing amplifier that computes how much V_{logi} has changed since the previous reset,

$$V_{di}(t) = \frac{C_1}{C_2} (V_{logi}(t) - V_{logi}(t_{reset}))$$

The reset signal itself is triggered whenever voltage V_{di} reaches either a positive V_H or negative V_L threshold. Therefore, two consecutive resets at t_1 and t_2 satisfy $V_{logi}(t_2) - V_{logi}(t_1) = (C_2/C_1)V_{H/L}$, or equivalently,

$$\begin{aligned} \frac{\Delta I_{phi}}{I_{phi}} &= \frac{I_{phi}(t_2)}{I_{phi}(t_1)} - 1 = \exp\left(\frac{C_2}{C_1} \frac{V_{H/L}}{V_o}\right) - 1 \\ &= \theta_{H/L} \end{aligned}$$

This means that the relative temporal change of light $\Delta I_{phi}/I_{phi}$ has reached an upper θ_H or lower θ_L contrast threshold. Whenever a pixel senses a

Neuromorphic Sensors, Vision, Fig. 2 Illustration of photo current average and spatial contrast computation over a one-dimensional section of a sensor. *Top*: sensed photo current from 50 pixels on a line, where around pixel 25 there is a step in light (circles) and computed average current using a diffusive network (crosses). *Bottom*: spatial contrast computation from the above photo currents and average currents

Neuromorphic Sensors, Vision, Fig. 3 Simplified circuit schematics of a typical temporal contrast computation pixel

Neuromorphic Sensors, Vision, Fig. 4 Illustration of temporal contrast (DVS) retina output. Retina contains an array of 128×128 pixels similar to those in Fig. 3. Whenever a pixel senses a change of relative light above a threshold, it sends out a positive (*white* in the figure) or negative (*black* in the figure) event. *Left*: The retina is observing a slowly moving head. The image is reconstructed from 40,000 events collected during 250 ms. The number of events collected per pixel is gray

coded. Background *gray* represents zero events, *brighter gray* represents a net positive number of events per pixel, and *darker gray* represents a net negative number of events per pixel. *Right*: recording from the same retina when observing a poker card deck browsed very quickly (in less than 1 s) in front of the retina. This recording contains 1000 events obtained during 634 μ s (microseconds)

temporal change of light reaching one of the thresholds, it sends out an “event,” which consists of the pixel coordinates and polarity of light change (x, y, p). This way, the sensor output is a “flow” of events representing the changing visual scene, without being constraint to any frame time.

Figure 4 shows illustrative examples of images reconstructed from recorded event flows from a 128×128 pixel temporal contrast retina (Serrano-Gotarredona and Linares-Barranco 2013), either for a slowly moving scene (Fig. 4 left) or from a very fast moving scene (Fig. 4 right).

potential. However, considering a ratio of 1000 synapses to 1 neuron, as observed in biological networks, the bottleneck in designing large- to very large-scale networks is likely to be integrating synapses and related connectivity. Artificial synapses with synaptic plasticity require three computational elements: generation of synaptic current, storage of synaptic weight, and plasticity calculation. Memristors present the advantage of combining these three elements in a single component with a surface area of only a few hundred square microns.

Memristive hardware artificial neural networks

Definition

Like biological networks, hardware neuromorphic networks are built up of neurons and synapses. The emergence of memristors, innovative electronic components with plasticity properties similar to those of synapses, offers a new technological solution for building neuromorphic VLSI.

Detailed Description

The design of analog silicon neurons has now been mastered (Indiveri et al. 2011), lowering computational cost down to a picojoule per action

Memristive Principle

Memristors were originally envisioned by Leon Chua in 1971 (Chua 1971; Strukov et al. 2008). He considered the memristor as a fourth elementary, passive, two-terminal component, based on capacitor-inductor duality, unlike the resistor. Among the many descriptions of the memristor phenomenon in the literature, we focus here on the one best suited to neuromorphic design.

A memristor can be roughly described as a resistor which value depends on the current passing through: the stronger the current, the lower the resistance. In other words, similar to biological synapses, the more a memristor is used, the easier it is to use.

Taking a closer view, this phenomenon is only operative above a threshold voltage. Below that threshold voltage, a memristor is equivalent to a resistor and follows Ohm's law. Above it, variations of the memristor resistance depend on the applied voltage (value and application period). Due to the present fragility of these components, the voltage is only applied for short, repeated periods (less than a few hundred nanoseconds), rather than a single, long period. Figure 1 illustrates variations in the memristor resistance, depending on the applied voltage pattern. The increase and decrease of the memristor resistance is reversible depending on the polarity of the applied voltage.

One very important point regarding memristor function is the associated memory phenomenon. There are several processes underlying memristors properties: thermal effect,

Neuromorphic Technologies, Memristors, Fig. 1 Pulse response of a simulated memristor showing resistance potentiation and depression. *Top*: Resistance pulse response. *Bottom*: Voltage pulse patterns applied to

the memristor. (a) Pulse response with a low voltage V_1 (V_1 is above the threshold voltage). (b) Pulse response with a higher voltage V_2 ($V_2 > V_1$). In this latter case, the potentiation and depression phenomena are faster

redox-related chemical effect, and electronic effect. However, all these processes rely on a modification in the material, which implies that the memristor resistance is maintained, even when it is no longer connected to an energy source.

To summarize, that single nano-component provides a value (resistance) dependent on events (voltage and time), a memory point, and an adaptation mechanism.

Memristive Hardware Artificial Neural Networks

The intrinsic properties of the memristor make it an excellent candidate to replace existing solutions for hardware synapses in neuromorphic analog VLSI: (i) capacitors, which require periodic refreshment of the voltage across their terminals; (ii) floating-gate transistors, which require high voltages to program the value stored on the

floating gate; and (iii) digital memory points, which require digital-to-analog converters.

However, as previously described, the memristor's plasticity depends on the voltage applied to the terminals, whereas classical plasticity in neuromorphic systems, known as spike-timing-dependent plasticity (STDP), depends on the relative timing of events. It is then necessary to convert the time difference between two action potentials into a difference in voltage at the memristor terminals (Linares-Barranco et al. 2011). This point is now solved by IC designers, and focus is now on enhancing the characteristics of memristors. Depending on the memristor technology, there may be a dissymmetry between the increase and decrease in value of the resistance, and/or the number of write cycles may not be suitable for industrialization, and/or the technology may not be directly compatible with standard VLSI process.

Memristors offer undeniable advantages for future design of very large-scale neuromorphic devices. Their present limitations should be

overcome in the near future, thus providing neuroscience with a new performing tool for investigating neuronal mechanisms.

NeuroMorpho.org

Ruchi Parekh and Giorgio A. Ascoli
Center for Neural Informatics, Structures, and Plasticity, Krasnow Institute for Advanced Study,
George Mason University, Fairfax, VA, USA

Definition

NeuroMorpho.Org is a freely accessible online database of three-dimensional digital

reconstructions of neuron morphologies that are described in the scientific literature. The goal of the project is to enable reuse of these valuable data for research and to encourage data-sharing in the neuroscience community (Ascoli 2006). To this aim, the project identifies publications containing neuronal reconstructions and contacts the authors asking them to make their data available to others (Halavi et al. 2012).

Detailed Description

New data is uploaded to the database periodically during version releases. Version 5.7, released in May 2014, included 11,335 reconstructions contributed by 144 laboratories worldwide from 24 species and 29 brain regions. These data represent more than 30,000 h of manual reconstructions and 72 m of traced axonal and dendritic branching. Since the first public release in August 2006, the website has received over 135,000 unique visits from 146 countries. More than 3.2 million reconstruction files have been downloaded and used in over 200 published articles.

Various reconstruction software systems exist to generate the 3D morphologies from microscopy (Parekh and Ascoli 2013). Each of these offers multiple options to customize the process according to individual user preferences, and every researcher typically makes different selections based on their scientific interests. As a result, reconstructions come in a variety of formats, each containing an assortment of details, occasional inconsistencies, and unique features. Hence, all contributed data undergo a standardization procedure, in which each reconstruction is processed, measured, imaged, annotated with relevant meta-data, and uploaded to the database (Halavi et al. 2008).

Each reconstruction's information page includes its metadata, an image, a link to the original publication, a set of measurements computed with L-Measure, a 3D animation, and direct access to online interactive visualization. Additionally, each reconstruction is included as both the standardized version and the original version from contributing authors, along with a log of

changes made during the standardization procedures as well as a list of notes addressing any other specific and relevant details. The standardized version of the reconstruction is available in the SWC format, but reconstructions can also be downloaded in NEURON, Genesis, and NeuroML formats.

Users can query the database via a number of functionalities on the website (Ascoli et al. 2007). Using the Browse By functionality, users can browse the database by species, brain regions, cell types, or archive names. With the Search By Metadata functionality, users can narrow their search by selecting filters within a number of categories such as species, brain region, cell type, experimental protocol, and contributing author to name a few. Cross-category searches generate even more specific results. Reconstructions can also be searched by morphological measurements with the Search By Morphometry functionality. Users can specify neuron tree types (apical or basal dendrite, axon, whole neuron) and combine 21 morphometric parameters with Boolean logic or ranges. The Search By Keyword function is yet another way to search the database using specific input queries (e.g., “dendritic targeting, non-fast spiking”).

The website also provides access to a database of mined publications in the Literature Coverage section. Publications identified as containing neuron reconstructions are classified based on the availability of reconstructions, and these can be further explored by their year of publication and details such as species and brain region. The Help section of the website includes a Quickstart guide that explains how to find and download reconstructions, an FAQs section, and useful Tools & Links related to neuron reconstructions.

One of the most common experimental goals of digital reconstruction is to establish neuronal identity. Nonetheless, data downloaded from the repository have a number of other applications in computational neuroscience and in educational outreach (Parekh and Ascoli 2013). The reconstructions can be used to design and validate anatomically realistic virtual models of neuronal growth and to provide detailed compartmental representations of membrane biophysics to run

electrophysiological simulations. Furthermore, the 3D digital formats of reconstructions make them ideally suited to run complex morphometric analyses and to estimate potential network connectivity.

Technical advancements in tissue processing, image acquisition, and morphological reconstruction are leading to high-throughput data collection. With the expected forthcoming deluge of information, data curation and management will continue to become even more necessary to maximize the opportunity for scientific discovery. Databases like NeuroMorpho.Org are crucial as they not only contribute to data storage and distribution but also help formulate standards for file sharing, metadata annotation, and ontology development to facilitate smarter searches.

Neuromuscular Control Systems, Models of

James J. Abbas

School of Biological and Health Systems
Engineering, Arizona State University, Tempe,
AZ, USA

Synonyms

[Models of neural control of movement](#); [Models of neuromotor control](#)

Definition

The neuromuscular control system is the network of neurons and muscles involved in the control of movement and posture. In many instances, the definition of the system also includes the sensors, sensory processing circuitry, and/or the passive mechanical structures that influence movement. Models of neuromuscular control systems, which are mathematical representations of one or more components, are used extensively in scientific investigations of neural control and in engineering development of biomimetic systems.

Detailed Description

An animal's ability to move is critical for exploration, interaction with the environment, and ultimately, survival. Neuromotor systems have been some of the most studied in neuroscience because movement is a readily observable behavior and the experimental environment can often be altered to manipulate the demands on the motor control system. The experimental paradigms and data derived from these studies have been used to form the theoretical foundations of our understanding of the neural control of movement and have had a broad impact on our understanding of neural systems that underlie the control of other physiological processes. Models of neuromuscular control systems provide a quantitative

representation that can be used in basic science investigations and for engineering applications.

Models of Neuromuscular Control Systems Have Been Used for a Variety of Applications in Science and Engineering

Models of neuromuscular control systems have primarily been used for developing and testing theories of motor control (Diedrichsen et al. 2010; Franklin and Wolpert 2011; Krakauer and Mazzoni 2011; Scott 2012; Scott and Norman 2003; Shadmehr and Mussa-Ivaldi 2012; Shenoy et al. 2013; Todorov and Jordan 2002; Wolpert and Kawato 1998). The complexity of the system components (sensory, neural, and motor) necessitates the use of computational approaches to quantitatively investigate and evaluate theories of motor control. Given the high degree of interaction between the sensory, neural, and motor components, it is often critical to include multidimensional dynamic models of the sensory as well as motor components in order to effectively use simulations of neural systems (Abbas and Full 2000; Cheng and Loeb 2008; Ekeberg 1993; Kambara et al. 2013; Pinter et al. 2012; Zelik et al. 2014).

Models of neuromuscular control systems have also been used in the design of biomimetic systems (Abbas 2011; Abbas and Abraham 2014; Ambroise et al. 2013; Bar-Cohen 2006; Schiff 2012; Verdaasdonk et al. 2009). There is a growing interest in the design of control systems that mimic neural systems in an effort to endow machines with sensorimotor control capabilities such as those exhibited by nearly all animals. Biomimetic systems have been used to control robots that walk (Verdaasdonk et al. 2009), robots that manipulate objects, and robots that autonomously interact with each other and the environment (Bar-Cohen 2006; Burdet et al. 2013). These efforts may not only produce robots with impressive capabilities, but they may also provide a real-world testbed for evaluating theories of motor control in a system that includes arrays of sensor and time-dependent actuators and that has to operate in a complex environment.

Finally, models of neuromuscular control systems have also been used extensively in the development of rehabilitation strategies and devices (Abbas and Riener 2001; Jung 2011; Peckham 2007; Scott and Norman 2003). For many years, one area of research and development has investigated the use of electrical stimulation to activate paralyzed muscles of people with spinal cord injury to restore functions such as standing or hand grasp, to enable exercise, or to facilitate neuromotor rehabilitation. In these systems, short electrical pulses delivered by electrodes generate action potentials in nerve fibers for the purpose of controlling movement or posture. A critical component of the technology, therefore, is the neural control system – i.e., that component of the technology that decides how to activate muscles in order to achieve the desired movement or posture. In some instances, the control systems have utilized very traditional engineering control approaches; other designs have utilized models of neural control structures. Computer-based studies that use movement simulation have been an important tool in the development of these neural control systems that use electrical stimulation. Although a large portion of this work has been directed at developing systems for people with spinal cord injury, models of neural control and movement simulation have also been used in the development of rehabilitation technology for individuals who have experienced a stroke or traumatic brain injury and for the development of advanced prosthetic limbs.

Sensory↔Neural↔Motor Interactions are Fundamental to Neuromuscular Control

In order to achieve effective interaction with the environment, neural control systems must gather data from the environment and have a means of acting on it. Control of movement involves a complex integration of sensory information to produce neural signals that activate muscles. Spatially distributed arrays of transducers gather information about the body and the external world, and the individual transducers have

response properties that are dynamic and non-linear (Kandel et al. 2013; Mileusnic et al. 2006). Furthermore, the sensitivity and dynamic range of the sensors can be actively modulated by the nervous system in a task-dependent manner. Action potentials in motor neurons generate muscle contractions that produce forces; the forces are transmitted to skeletal segments through tendons. In a given motor unit, the timing and frequency of action potentials in the motor neuron are determined by the properties of the motor neuron itself and the pattern of inputs it receives from the neural control system. The dynamic processes of muscle contraction and movements of skeletal segments (Abbas and Full 2000; Cheng and Loeb 2008; Chiel et al. 2009; Pinter et al. 2012; Ting et al. 2012; Zelik et al. 2014) all have time constants that are much greater than the neural dynamics and a large amount of the sensory information delivered to the neural control system is derived directly from muscles and tendons.

For the investigator studying the neural control system, the implications of this complex interaction are clear: the neural control system should not be studied in isolation. The sensors and actuators have dynamic properties that are actively modulated by the nervous system and that strongly influence the nervous system. These sensory-neural-motor interactions are not only important for the successful completion of any given task, but the interactions are also likely to be a major contributing factor to the versatility of neural control systems.

The Use of a Priori Knowledge Is Fundamental to Motor Control

Many observations in motor control experiments suggest that the nervous system uses a priori knowledge (or estimates) of the physical properties of the system to be controlled in order to deliver appropriate patterns of motor signals. This basic idea is embedded in several widely used theories of motor control, such as motor programs, internal models (Davidson and Wolpert 2005; Franklin and Wolpert 2011; Krakauer and Mazzoni 2011; Todorov and Jordan 2002;

Wolpert and Kawato 1998), central pattern generators (Abbas and Full 2000; Ekeberg 1993; Grillner et al. 2008; Verdaasdonk et al. 2009), and synergies (Bicchi et al. 2011; Duysens et al. 2013; Gentner et al. 2013).

In the control of single-segment movements, knowledge of the inertial load is used to modulate the amplitude and duration of muscle activation patterns; in multi-segment systems, knowledge of the intersegmental dynamics is used to produce coordinated movements. The use of such knowledge is apparent in ballistic tasks, such as throwing a dart, as well as repetitive tasks, such as walking.

In addition to using estimates of the physical properties, the nervous system can also utilize estimates of the noise in the environment to influence motor outputs. A simple, yet readily observable, example of how the nervous system uses estimates of the noise is to compare muscle activation patterns when standing on a bus as it moves from a smooth, paved road onto a bumpy, unpaved one. In both cases, the objective is to stand upright on a moving vehicle, but the expectation of noise on the bumpy portion of the road would alter motor outputs in a manner that stiffens the body in order to stabilize it.

An important implication of this use of *a priori* knowledge is that it enables anticipatory, rather than reactive, activation of muscles. Given the long time constants for activation of muscles and the high inertia of the body and external loads, this anticipatory activation is essential for many tasks. For example, in human walking, the anticipatory activation of the knee extensors prior to foot contact ensures sufficient knee extension torque to support the transfer of body weight to the lead limb.

Models of Neuromuscular Control

As with any modeling exercise, the form and characteristics of a model of neuromuscular control will be selected to meet the needs of the task at hand, and the only meaningful definition of a “good” model is one that helps to solve the problem being addressed. Over the past several

decades, a wide range of models of neuromuscular control have been developed and utilized; a few general forms of models are briefly described below.

Feedback Control Models

Some, but not all, sensory inputs to the neural control system provide feedback. The smell of freshly baked bread from the next room provides input that may strongly influence the activities of the motor control system, but does not provide information that is a result of ongoing motor activity. In contrast, while reaching to grasp a piece of that bread, the sensory inputs from visual, proprioceptive, and tactile sensors provide feedback – i.e., information that is a result of ongoing motor activity. Such feedback plays a critical role in most neuromotor activities and is therefore included in many models of neuromotor control.

Some of the earliest and most basic quantitative models of the neural control of movement used traditional feedback control system structures. The system to be controlled (i.e., the “plant”) was modeled using a linear transfer function and negative feedback produced activation that regulated position about a setpoint. Pioneering studies used models that included linear components to describe the control of eye movements (Cook and Stark 1967; Robinson 1973; Young and Stark 1963) and control of the cardiovascular system (Katona et al. 1970).

The primary advantages of using a linear systems approach are that the model parameters can be derived using input/output data and the relatively simple structure of the model enables extensive mathematical characterization and analysis. However, for most models of biological systems, this model structure is insufficient because it fails to capture important nonlinear properties, it fails to capture the time-varying characteristics, and it is over-reliant on feedback. Over the past several decades, there have been substantial advances in the development and use of models of neuromotor control systems that have specifically addressed these and other shortcomings of the linear systems approach (Franklin and Wolpert 2011; Marmarelis 1997; Ting et al. 2012; Todorov and Jordan 2002).

Although there are clearly shortcomings to the linear feedback model, the concept of negative feedback is used in many models of neural control that use nonlinear or adaptive approaches (Jung et al. 1996; Krakauer and Mazzoni 2011; Marmarelis 1997; Morasso et al. 1999; Todorov and Jordan 2002; Wolpert and Kawato 1998) to achieve a higher degree of biological fidelity.

Motor Programs

An early form of a model that has been used to explain or implement anticipatory activation is the notion of a “motor program.” In this formulation, the nervous system has a set of pre-stored patterns of activation (programs) that it can replay to perform a specific task. The program may activate a set of muscles to produce coordinated movements, and simple scaling rules may explain some of the versatility that would be required to make the same movement with different loads. Although this basic idea may be attractive, in its purest sense it does not adequately describe an animal’s ability to produce a rich set of behaviors in a complex environment. A more complex version of the motor program idea may be consistent with recent neurophysiological evidence (Esposito et al. 2014).

Internal Models for Predictive Control

The notion of an internal model has been extensively used to explain many observations in motor control. The internal, or forward, model predicts the relationship between actions and their consequences (Shadmehr and Mussa-Ivaldi 2012; Shadmehr et al. 2010; Wolpert and Kawato 1998) and therefore enables much more than simply stereotyped actions. The internal model may include representations of the muscle dynamics, limb dynamics, as well as the environmental load and sensory response properties. This approach has been utilized in a number of model systems (Davidson and Wolpert 2005; Franklin and Wolpert 2011; Krakauer and Mazzoni 2011; Todorov and Jordan 2002; Wolpert and Kawato 1998).

The support for an internal model has been greatly strengthened by studies that require motor learning (Shadmehr and Mussa-Ivaldi

1994; Shadmehr and Mussa-Ivaldi 2012). In a paradigm in which subjects were asked to move a manipulandum in a center-out-and-back pattern, the movements in an unloaded condition follow a straight path. After an unnatural external force field is imposed, movement patterns are initially nonlinear, but subjects eventually learn to adjust motor activation patterns in order to restore the linear out-and-back trajectories. Most importantly, the movement patterns are disrupted after the force fields removed in a manner that would be predicted by an internal model that incorporates a model of the unnatural force field in the environment (Shadmehr and Mussa-Ivaldi 1994).

Although there is strong evidence in support of internal models for predictive control, the specific neurophysiological structures that may instantiate such a model have not been identified. The cerebellum has been viewed as a likely source of the computation and adaptation involved in implementation of an internal model (Moberget et al. 2014), and there is indirect evidence from clinical observations of people with cerebellar disorders (Izawa et al. 2012). However, the nature of a putative internal model and the neurophysiological basis for it are active areas of research.

In some views, the internal model is used by the nervous system for optimal control – i.e., control that uses specific criteria to maximize performance and minimize cost (Diedrichsen et al. 2010; Franklin and Wolpert 2011; Todorov 2004; Wolpert et al. 1995). This notion of optimal control has been extensively employed, but the extent of its utility has been questioned (de Rugy et al. 2012; Loeb 2012). One important logistical problem in quantitatively evaluating the theory is that the cost function has to be known, or assumed. If one produces a cost function that is optimized by a particular movement, this does not prove that the nervous system optimized the movement (this is akin to the observation that “correlation does not prove causation”). Perhaps, more importantly, most observations of biological control systems that provide evidence for “optimal” control may also be viewed as supporting a theory of “just good enough” control (Loeb 2012). This is an active area of debate and is likely to be an active area of research in the future.

Central Pattern Generators

The concept of a central pattern generator (CPG) is often used to describe the neural control of cyclic movements such as walking, breathing, swimming, or chewing. The foundation of this model of neuromotor control is a group of neurons that produces a cyclic pattern of activity in motoneurons in order to produce cyclic movements. There is a wide range of evidence in many species indicating that both cellular and network structures may contribute to the generation of the observed oscillatory patterns and that these patterns are strongly influenced by sensory inputs (Grillner et al. 2008; Harris-Warrick et al. 1995; Ivanenko et al. 2009; Kandel et al. 2013; Tazerart et al. 2008; Van de Crommert et al. 1998). Note that in many systems there is little or no evidence to support the existence of a CPG that is capable of oscillating in the absence of sensory input, and, in many cases, well-timed sensory feedback is essential to produce functional oscillatory patterns. In addition, although the representations often depict a CPG as a group of neurons that is distinct from all other neural structures, it is clear that the neurons involved in producing oscillatory patterns are not distinct populations and can be involved in other aspects of motor control such as non-oscillatory movements, reflexes, and/or coordination.

Mathematical models of CPG systems can be implemented using a set of equations that describe a general oscillator (Ermentrout and Terman 2010; Izhikevich 2010; Schultheiss et al. 2012) or equations that are based on the fundamental biophysics of the neuron membrane (Ekeberg 1993; Grillner et al. 2008; Jung et al. 1996). The biophysical models typically have a capacitive membrane with passive conductance channels as well as active channels that may be voltage and time dependent (Grillner et al. 2008; Kandel et al. 2013). The network connections among neurons in the model also contribute to the oscillatory behavior. Reciprocal inhibition or self-inhibition can be used as a mechanism to contribute to the termination of a burst (Grillner et al. 2008). Mutual inhibition between two sides of an oscillator can be used to silence one side while the other is active (Grillner et al. 2008).

While the core structure of the model produces the basic oscillatory pattern, most CPGs also require mechanisms to modulate their patterns of activity in order to produce functional movements. Inputs to the CPG can be used to initiate/terminate oscillatory activity or to alter the frequency or duty cycle of the oscillatory pattern. Sensory signals can also alter the oscillatory pattern by mechanisms that affect movement amplitude, frequency, or duty cycle (Grillner et al. 2008). Phase resetting can occur when a sensory input alters the pattern in a manner that shifts the phase of oscillatory pattern; the phase dependence of the response to such inputs enables a variety of behaviors (Ermentrout and Terman 2010; Schultheiss et al. 2012).

Synergies

The musculoskeletal structure of many animals enables production of a number of movements to perform a rich set of tasks. Multiple muscles articulate many degrees of freedom of movement of the skeletal structure. One consequence of this versatile arrangement is that there are often multiple options to achieve a given task. There is kinematic redundancy in that many postures can achieve the same goal: for example, I can reach to grab the cup in front of me with my elbow tucked in close to the body or with it pointing out to the side. There is also kinetic redundancy in that many patterns of muscle activation can achieve the same set of joint moments to produce a movement. The redundancies provide clear advantages by affording options for task execution that may be essential in a given environment (e.g., keeping my elbow close to the body when I reach for that cup of coffee while seated on a plane), but it also poses a dilemma in that the neural control system must “choose” from a number of feasible options.

Synergies have been incorporated into many models of neuromotor control to reduce the number of degrees of freedom and therefore solve the “redundancy problem.” In this model, the nervous system is structured in a manner that it preferentially activates groups of muscles in a particular pattern in order to produce a complex movement. For example, a flexor synergy has been proposed as a means of using a single command for flexion

to drive the hip, knee, and ankle extensors and therefore generate a coordinated limb flexion movement (Duysens et al. 2013). In addition to being used for voluntary task execution, synergies may also be utilized to produce coordinated reflex actions and may facilitate learning. The organization of muscles into synergies may be incorporated into an internal model structure or into the central pattern generator structure (Duysens et al. 2013). In either of these arrangements, the synergy could facilitate movement execution, feedback, and motor learning, but the extent to which synergies explain the organization of motor systems may be limited (de Rugy et al. 2013).

NEURON

Definition

NEURON is a simulation environment that is primarily used for creating and using computational models of individual neurons and networks of neurons.

Detailed Description

This entry surveys key aspects of the NEURON simulation environment (NEURON hereafter). For more detailed coverage of these and related topics, please see *The NEURON Book* (Carnevale and Hines 2006), documentation at NEURON's web site neuron.yale.edu, or our chapter on numerical integration (Carnevale and Hines 2014).

Domain of Utility

NEURON is a “domain-specific” simulator in the sense that, by design, it has features that make it particularly well-suited for constructing and simulating certain kinds of models. It emerged from a collaboration between John Moore and Michael Hines at Duke University. Their initial aim was to develop software for models used to complement experimental research on spike initiation and

conduction in squid axon (Hines 1992, 1994). NEURON's domain of utility subsequently broadened in response to requests and contributions from other neuroscientists who began to adopt their software and apply it to a much wider range of problems (see neuron.yale.edu/neuron/credits).

At the center of this domain are anatomically detailed models of biological neurons with detailed anatomical structure and complex membrane properties and networks of such neurons. It has also been used to implement and simulate models as diverse as networks of artificial spiking cells (Lytton and Omurtag 2007, ModelDB accession number 105507); hybrid nets that combine artificial spiking cells and mechanistic models of biological neurons (Yu et al. 2013, ModelDB accession number 144570); cardiac muscle cells (Courtemanche et al. 1998, ModelDB accession number 3800); and networks of arteriolar smooth muscle (Crane et al. 2001, ModelDB accession number 3785). For a more complete perspective on the range of models that have been implemented with NEURON, see the NEURON Bibliography neuron.yale.edu/neuron/static/bib/usednrm.html.

Software and Hardware Requirements

NEURON runs under all currently popular operating systems (UNIX/Linux/macOS and MS Windows) on hardware that ranges from Mac and PC laptops to high-performance computing environments such as workstation clusters and massively parallel supercomputers.

Development and Project Support

NEURON is under active development, with support from NIH. It uses an open-source development strategy, with all source code available from the nrm and iv repositories at github.com/neuronsimulator, so interested individuals may start their own private development forks. Contributions of code or programming effort to NEURON's official repository are encouraged, but all decisions about what is included in that repository and official releases of NEURON are up to the final judgment of Michael Hines.

User Base

As of this writing, there are more than 2000 NEURON users; over 1500 are registered with the NEURON Forum, and the others subscribe to the old NEURON mailing list. In recent years, each annual meeting of the Society for Neuroscience includes about 50–60 presentations that report new work that involves NEURON, and new publications that used NEURON are appearing at a rate of >120 per year; the total number of such publications is currently >2100 (see the NEURON Bibliography, discussed above in “[Domain of Utility](#)”). Authors of many of these articles have shared their source code via ModelDB, which currently contains more than 670 NEURON models (see senselab.med.yale.edu/modeldb).

User Support

Documentation

The NEURON Book provides detailed information about NEURON and its internals (especially the standard run system), as well as numerous usage examples. Links to the Programmer’s Reference, tutorials on common tasks, and key publications about NEURON are posted at the online documentation page neuron.yale.edu/neuron/docs.

Support on Specific Topics

The NEURON Forum neuron.yale.edu/phpBB is an online resource where users may ask questions and share their own expertise. Currently it has more than 16,000 posts in over 3800 question-and-answer threads. Additional support is available by telephone and email for those who have more specialized problems or prefer confidentiality.

Courses

Since 1998 the NEURON development team has presented a 1-day “executive summary” course at most annual meetings of the Society for Neuroscience and a multiday intensive hands-on course in spring or summer at academic institutions and research centers such as UC San Diego, HHMI/Janelia, Wright State University, Emory University, and University of Minnesota. We have also

presented a range of courses on NEURON at other venues, including KAIST www.kaist.edu in Daejeon, Korea (2010), and IST ist.ac.at in Klosterneuburg, Austria (2012).

Models in NEURON

A NEURON model may involve one or more cells and may include any combination of “biophysical model cells” and “artificial spiking cells.” These terms have particular meanings in the NEURON simulation environment. The term “biophysical model cell” implies a mechanistic representation of a cell or an isolated part of a cell that requires numerical integration of the cable equation or of at least one ordinary differential equation.

The term “artificial spiking cell” is reserved for a particular subset of what are broadly called “integrate and fire cells”: those whose behavior is defined by equations that have analytical solutions. Artificial spiking cells can be simulated extremely efficiently, because the future values of their states can be calculated directly from their current values. Such a cell imposes no computational burden until it receives an input; furthermore, when an input arrives, the cell’s states can be updated by mere algebraic calculation, which is orders of magnitude more efficient than numerical integration (see Chap. 10 in Carnevale and Hines 2006).

Interactions between cells in a network model may include any of the following:

- Synaptic transmission, which may involve use-dependent and/or associative plasticity. The pre- and postsynaptic cells may be any combination of biophysical model cell and artificial spiking cell. Two kinds of synaptic transmission can be represented:
 - Spike triggered: the effect on the postsynaptic cell depends only on the fact that there was a presynaptic spike. The pre- and postsynaptic cells may be any combination of biophysical model cell and/or artificial spiking cell. Note that artificial spiking cells may interact with other cells only by spike-triggered synaptic transmission.
 - Continuous transmitter release: the effect on the postsynaptic cell varies continuously as

a function of a time-varying quantity in the presynaptic cell.

- Gap junctions.
- Ephaptic interactions.
- Molecular diffusion across the extracellular space (Newton et al. 2018).

Programming with NEURON

NEURON can be used as a general-purpose programming environment for problems that have nothing to do with computational neuroscience, but its primary use is for building models and running simulations. Models may be created, managed, and used to generate publication quality results in any of the following ways:

- Writing statements in any combination of hoc and/or Python
- Using GUI-based tools such as the CellBuilder or Network Builder
- Combined use of GUI-based tools and user-written code

General-purpose C code can also be embedded in VERBATIM blocks in NMODL files (see “[Program Architecture](#)” below) and called by hoc or Python statements.

In addition to being controllable via hoc or Python, NEURON binds these two languages together, allowing functions written in Python to call hoc or vice-versa. NEURON’s hoc has been considerably extended beyond the simple language originally described by Kernighan and Pike (1984). The principal additions include object-oriented programming, a graphical user interface, and features specifically useful for implementing mechanistic models of biological neurons and networks of neurons, e.g., “sections,” which represent unbranched neurites (cables) and have anatomical and biophysical properties. Python provides access to the wide range of analysis and visualization libraries available for that language, online help, vector arithmetic, a more object-oriented interface, and richer return types for NEURON methods. NEURON’s neuroscience-specific graphics classes (PlotShape, RangeVarPlot) offer dedicated support for use with Python graphics.

NEURON’s reaction-diffusion module (neuron.rxd (McDougal et al. 2013; Newton et al. 2018)) provides a compact specification for defining intracellular and extracellular chemical dynamics without regard to numerical integration details. This allows users to focus on key aspects of the model itself, such as region (e.g., extracellular, ER, cytosol), species (e.g., IP3, calcium), and reactions or state transitions. In recent versions, reactions are just-in-time compiled, and 3D deterministic simulations employ a threaded version of the Douglas-Gunn alternating direction implicit method to achieve high runtime performance. Species declared using the neuron.rxd module may be used to modulate channel dynamics defined in, e.g., NMODL, and their concentrations automatically change in response to corresponding currents computed in NMODL. Local dynamics specified using neuron.rxd are exportable to SBML for use with other simulators.

GUI Tools

NEURON has a suite of graphical tools that can be used to build models and generate publication-quality results without having to write a single line of program code. These tools can also be employed in conjunction with user-written code to exploit the complementary strengths of programming and the GUI. They are especially helpful when interactive use is beneficial, e.g., in model development, debugging, and exploration of model properties and behavior. There are too many to list and describe here, but the following deserve special mention.

Import3D

Converts detailed morphometric data into models. Accepts Eutectic, SWC, NeuroLucida version 1 and 3 text files, and MorphML files and can export the results as reusable hoc code or to a CellBuilder. Reports errors found in morphology data and can be used to diagnose and fix errors.

Channel Builder

Creates new voltage- and/or ligand-gated ion channels specified either by Hodgkin-Huxley style ordinary differential equations or as Markov

schemes. Gating may be deterministic or stochastic (Hines and Carnevale 2005).

CellBuilder

Builds and manages properties of model cells. Simplifies specification of algorithmically controlled spatial variation of biophysical properties. Can automatically discretize models according to the d_lambda rule, which ensures that compartment length is no longer than a user-specified fraction of the AC length constant at 100 Hz (Hines and Carnevale 2001, 2005; Carnevale and Hines 2014). Can export source code in hoc for cell classes that are reusable, e.g., for network models (Hines and Carnevale 2008); can also import and export level 2 NeuroML for compatibility with other simulators.

Network Builder

Prototypes small networks. Can export source code in hoc that may be mined for reusable components such as cell classes.

Linear Circuit Builder

Adds linear circuit elements (resistors, capacitors, inductors, op amps) to a model, e.g., to represent microelectrode properties, dynamic clamp, gap junctions, ephaptic interactions, extracellular stimulation, or generation of extracellular fields. Can export reusable hoc code that may be combined with user-written code.

Impedance Tools

Analyze a model cell's electrical signaling properties, computing and displaying its "electrotonic transformation" (Carnevale et al. 1995, 1997; O'Boyle et al. 1996), input and transfer impedances, and voltage attenuation and transfer ratios.

Model View

Generates a concise, browsable textual and graphical summary of the properties of a model cell, as it exists in the computer after execution of model setup code. This is extremely useful when working with models that are specified in procedural programming languages. To the best of our knowledge, no other simulator that employs

procedural model specifications has a similar feature. The Model View tool can export level 1 and level 2 NeuroML for compatibility with other simulators.

Variable Time Step

Analyzes a model's system equations and automatically selects the most appropriate adaptive integrator. Facilitates manual specification of the state error tolerances that govern step size and integration order and can automatically select appropriate error tolerance for all state variables (Carnevale and Hines 2014).

Model Setup and Simulation Execution

Before a simulation can be run, NEURON executes the user's "model specification" which defines the properties that are to be represented in a model. This results in the creation of internal data structures that reflect the model's system equations and will be used during simulation execution. Model setup typically takes much less time than simulation execution does, because setup only needs to be done once, whereas executing a simulation requires numerical integration of the model's system equations, which is computationally very costly, especially if many time steps are involved.

NEURON has a powerful and flexible standard run system for controlling and coordinating the sequence of actions that occur during simulation execution. At a minimum, each "run" consists of two phases that are performed by compiled routines operating at machine code speed: initialization and solution of an initial value problem based on the model's system equations. The main loop that supervises this process is written in hoc, but most runtime is consumed by numerical integration, even though that is done by compiled code.

Much of the standard run system is implemented in hoc, and users can modify it as necessary in order to accomplish additional tasks such as:

- Preprocessing of input data, e.g., in order to modify the model specification or to serve as input signals that are applied to a model during solution generation.

- Custom initialization (often required for complex models, especially those that involve ion accumulation mechanisms).
- Postprocessing simulation results, e.g., to extract measures such as firing rates.

NEURON also has an event system that is an important complement to the standard run system. Indeed, events make it possible to use a few hoc or Python statements to implement complex “virtual experimental protocols” such as predetermined or conditional perturbations of one or more model parameters that might otherwise have required much tweaking of the standard run system.

Parallel Simulation Execution

NEURON supports three styles of parallel simulation: multithreaded, bulletin-board style, and distributed simulation. These can be used individually or in any combination.

Multithreaded parallel simulation is suitable for machines with multicore (i.e., shared memory multiprocessor) CPUs. It is very easy to use since little or no change to source code is required. It is most useful for small nets and complex models of individual cells. However, speedup is sublinear because of interprocess communication overhead.

In bulletin board style parallel simulation, a “master” processor posts tasks to a “bulletin board.” “Worker processors” take tasks from the bulletin board and return results to the master via the bulletin board. This is particularly suitable for “embarrassingly parallel problems,” i.e., running large numbers of simulations, as is often necessary to evaluate plasticity and learning rules, optimize models, or explore parameter space. Interprocessor communication is managed by MPI (www.mpich.org). Converting a serial program to a form that is suitable for bulletin board parallel execution requires relatively minor modification of model source code. Load balance is achieved automatically, and speedup is very nearly proportional to number of processors.

Distributed simulation involves breaking a model into multiple parts so that each processor deals with a subset of the model’s system equations; again, interprocessor communication is managed by MPI. Parallelizing a serial program

may require considerable modification to source code, paying special attention to achieving good load balance. In NEURON, even individual neurons can be split into pieces and distributed over multiple processors for the sake of load balance (Hines et al. 2008a, b). With good load balance, speedup is very nearly proportional to number of processors as long as each processor has enough work to keep busy (200 or more states that require numerical integration) (Migliore et al. 2006).

Program Architecture

NEURON’s computational engine is implemented in compiled code, mostly C and C++. The GUI tools are implemented mostly in hoc, an interpreted language with syntax similar to C (Kernighan and Pike 1984); some tools such as Import3D and Model View also rely on some Python code, and the Print and File Window Manager is implemented in compiled code.

A compiled language called NMODL is available for adding new equations (algebraic equations, ordinary differential equations (ODEs), and kinetic schemes), state machines, and arbitrary C code in order to implement such things as new biophysical mechanisms (e.g., voltage- or ligand-gated channels, transport mechanisms, synaptic mechanisms), artificial spiking cell classes, and mathematical functions. There are also classes that can be used to add new linear equations that implement electrical circuits made out of linear elements (via the Linear Circuit Builder GUI tool) and sets of ODEs and kinetic schemes that specify the properties of voltage- and ligand-gated ion channels (via the Channel Builder GUI tool). Reaction-diffusion can be implemented with NMODL, but a more flexible multiscale approach is to use the `neuron.rxd` module described above.

CoreNEURON

A major target of active development in NEURON is to reduce both memory usage and runtime for large models on modern nonuniform memory architectures, such as Intel Xeon Phi and NVIDIA GPU, in which multiple memories range widely with respect to size and bandwidth/latency. To this end we are working on CoreNEURON (Kumbhar

et al. 2019; CoreNEURON github repository (2019)), a library for NEURON that enables simulations of models up to 7 times larger than would ordinarily fit into memory, while achieving a speedup of up to 5–7 times compared to what is ordinarily possible on the same hardware. Most existing NEURON models require little or no change to be executable by CoreNEURON. By default, simulation results are numerically identical between NEURON and CoreNEURON; optionally selectable performance optimizations are available which cause differences due to accumulation of double precision round off errors.

CoreNEURON's advantages result from extracting and optimizing NEURON's computational engine, meaning just the part of NEURON that is directly responsible for numerical solution of the equations that describe the model itself. Since CoreNEURON omits everything that is not essential for simulation execution, the process of translating a model specification from source code (hoc, Python, NMODL) into a form suitable for simulation execution can leave out a great deal of detail that regular NEURON would have needed – and that is why it can handle much larger models. CoreNEURON's optimizations primarily involve revising memory layout to make more efficient use of modern CPU and GPU architectures, e.g., by vectorization of model data structures, and avoidance of data transfer overhead.

Numerical Methods

Models that involve biophysical model cells with significant spatial extent and anatomical branching are equivalent to families of partial differential equations with boundary conditions as needed at their ends to implement coupling at branch points. NEURON generates approximate solutions to initial value problems involving these equations by numerical integration of the ordinary differential equations that result from spatial discretization of the cable equations. Its spatial discretization strategy uses the central difference approximation to the second spatial derivative of membrane potential; consequently simulations have second-order accuracy in space.

NEURON offers several different numerical integration methods and is implemented in such

a way that one may switch from one integrator to another without having to revise a model's source code. The default integrator for fixed time step solutions is fully implicit Euler, which has first-order accuracy in time and excellent stability. Also available are Crank-Nicholson, which has second-order accuracy in time but can generate spurious oscillations if a model's equations are too stiff, and a collection of adaptive integrators that automatically adjust time step and integration order to satisfy user-specified local error criteria. Simulations of networks with multiple cells connected by spike-triggered synaptic transmission can optionally use “local variable time step” integration, in which each cell has its own independent time step and integration order that are automatically adjusted. Selection of the most appropriate adaptive integrator and determination of relative error scale factors for each state variable are simplified by the VariableTimeStep tool, a GUI-based tool that can automatically determine the necessary settings. Readers who seek more information about these methods are referred to Carnevale and Hines (2014) or Chaps. 4 and 7 in *The NEURON Book* (Carnevale and Hines 2006).

Acknowledgments This work was supported by NIH award R01NS011613. The growing list of individuals who have made significant contributions to NEURON's development is posted at www.neuron.yale.edu/neuron/credits

Neuronal Avalanches

Dietmar Plenz¹ and Woodrow Shew²

¹Section on Critical Brain Dynamics, National Institute of Mental Health, Bethesda, MD, USA

²Department of Physics, University of Arkansas, Fayetteville, AR, USA

Synonyms

Balanced propagation; Critical branching process; Neuronal cascades; Power-law distributed patterns; Scale-invariant patterns

Definition

Spatiotemporal patterns comprised of local neuronal activity events that follow scale-invariant statistics. Pattern statistics is quantified by a power law distribution in pattern size, s , and pattern duration, t . The balanced propagation of activity during avalanche unfolding takes on the form of a branching process. Specifically, the probability distribution $P(s)$ takes the functional form of a power law $P(s) \sim s^{-\alpha}$, with exponent $\alpha = 3/2$, and $P(t) \sim t^{-\beta}$ with $\beta = 2$. The branching parameter, σ , estimated by the ratio of future to current events during an avalanche is critical, i.e., $\sigma = 1$. On average, neuronal activity neither grows nor decreases during avalanching.

Detailed Description

History of Neuronal Avalanches

Experimentally, neuronal avalanches were first identified in 2003 in the spontaneous activity of cortex slice cultures and cortex slices from rat (Beggs and Plenz 2003). The scale-invariant

nature of avalanches signifies a specific order in the commonly observed strong fluctuations of spontaneous brain activity. Such scale-invariance is in line with early suggestions by Per Bak (Stassinopoulos and Bak 1995; Bak 1997) that the brain should self-organize into a critical regime where avalanches of activity allow neurons to flexibly establish input-output relationships. Early implementation of neural networks (Chen et al. 1995; Eurich et al. 2002; Zhao and Chen 2002) derived from the Olami-Feder-Christensen model for earthquakes (Olami et al. 1992) introduced the formation of scale-invariant activity cascades in threshold-coupled neuron-like elements. Experimental confirmation of avalanches in spontaneous neural activity quickly progressed from in vitro systems including dissociated cortex cultures and leech ganglia (Mazzoni et al. 2007; Pasquale et al. 2008) to in vivo meso-scale LFP recordings in rodents (Gireesh and Plenz 2008) and nonhuman primates (Petermann et al. 2009; Priesemann et al. 2009), rodent spiking activity (Ribeiro et al. 2010) and macroscale recordings in humans using fMRI (Fraiman et al. 2009), EEG and ECoG (Solovey et al. 2012; Priesemann et al. 2013), and MEG (Palva et al. 2013; Shriki et al. 2013). Latest technological advances allowed neuronal avalanches to be identified in local pyramidal group activity in cortical layer 2/3 using 2-photon imaging with genetically encoded intracellular calcium (Bellay et al. 2015) and voltage-sensitive indicators (Scott et al. 2014). Latest conceptual developments demonstrate neuronal avalanches in vivo to be exclusive to the awake state (Scott et al. 2014; Bellay et al. 2015; Fagerholm et al. 2016) and to provide a statistical framework for the variability encountered in sensory evoked responses when accounting for systematic changes in event rate during responses (Yu et al. 2017). Theory and simulations predict that networks with neuronal avalanches are positioned at a critical point where they optimize numerous aspects of information processing (e.g., Kinouchi and Copelli 2006). This was experimentally confirmed for dynamic range (Shew et al. 2009) and information capacity (Shew et al. 2011; Yang et al. 2012) in cortex slice cultures and recently in vivo (Gautam et al.

2015; Fagerholm et al. 2016) (for review see Chialvo 2010; Shew and Plenz 2013; Hidalgo et al. 2014). Moreover, recent ex vivo experiments in turtle suggest that adaptation to visual input may maintain neuronal avalanche dynamics in visual cortex (Shew et al. 2015; Clawson et al. 2017). Importantly, systematic deviations from avalanche dynamics have been identified in abnormal brain dynamics such as epilepsy, schizophrenia, and sleep deprivation (Worrell et al. 2002; Osorio et al. 2010; Meisel et al. 2012, 2013, 2015; Milton 2012; Arviv et al. 2016; Seshadri et al. 2018). These dependencies on brain state as well as neurotransmitters that regulate the excitation/inhibition balance, such as GABA_A and glutamate (Beggs and Plenz 2003; Stewart and Plenz 2006; Mazzoni et al. 2007; Shew et al. 2011; Gautam et al. 2015), the neurotransmitter acetylcholine (Pasquale et al. 2008), and the neuromodulator dopamine (Stewart and Plenz 2006; Gireesh and Plenz 2008; Beggs and Plenz 2003; Mazzoni et al. 2007; Pasquale et al. 2008; Shew et al. 2011) suggest that the brain actively maintains avalanche dynamics. A subset of neuronal avalanches termed coherence potentials identify avalanches of high temporal coherence across space in analogy to propagating structures in turbulent flow or “gliders” in the game of life (Thiagarajan et al. 2010; Plenz 2012). For reviews on criticality and neuronal avalanches see (Chialvo 2010; Plenz 2012; Hesse and Gross 2014; Plenz and Niebur 2014; Cocchi et al. 2017; Muñoz 2017).

Data Sets and Critical Exponents

A dataset consisting of simultaneous, continuous recordings of local activity from numerous sites forms the basis of avalanche analysis. Continuous recordings are typically comprised of single neuron spike densities (2-photon imaging), the local field potential at a single electrode, fMRI single voxels, single electrode EEG and ECoG, or single sensor MEG activity. By simultaneously observing these activities from many sites, statistical inferences can be made whether activity at one site might relate to subsequent activity on other sites. The essential transformations require

(1) thresholding of local, continuous activity to obtain the amplitude and time of significant local neuronal activity events and (2) the clustering of spatially distributed events based on their temporal proximity. Thus, at its core, avalanche analysis involves three parameters: (a) the threshold thr , a temporal resolution Δt , and spatial resolution Δd . This general approach is motivated by the insight that information on causal spatial interactions between elements in a network is often not experimentally accessible, yet, if these interactions exist, they should give rise to temporal dependencies in the form of activity cascades. Specifically, spatiotemporal activity cascades are defined as neuronal avalanches only if the probability distribution $P(s)$ of cascade size s takes the functional form of a power law $P(s) \sim s^{-\alpha}$, with exponent $\alpha = 3/2$ and the probability distribution of lifetimes is $P(t) \sim t^{-\beta}$ with $\beta = 2$. The branching parameter, σ , estimated by the ratio of future to current events during an avalanche is $\sigma = 1$, i.e., critical, that is, on average neuronal activity neither grows nor decreases during avalanching. These exponents are predicted by the theory of branching processes (Harris 1963; Larremore et al. 2012) or high-dimensional directed percolation (Muñoz et al. 1999; Buice and Cowan 2009) and are most commonly found in more biologically realistic models of avalanche dynamics (de Arcangelis et al. 2006; Levina et al. 2007; Meisel and Gross 2009; de Arcangelis and Herrmann 2010; Millman et al. 2010; Poil et al. 2012; Rybarsch and Bornholdt 2014a; Hernandez-Urbina and Herrmann 2017). The empirical determination of these critical exponents, though, is challenging and requires elaborate scaling analyses based on large data sets as shown in the original publication of neuronal avalanches (Beggs and Plenz 2003). Such scaling analysis is often limited by the size of the available data set supporting a more relaxed definition of neuronal avalanche identification with, e.g., power law slope $\alpha = 1-2$ as a first pass. This exponent range still implies that the mean size of cascades diverges in an infinite system. Conversely, cascades that fail to demonstrate power law statistics are not considered neuronal avalanches (Fig. 1).

Methods of Neuronal Avalanche Data Analysis

Step 1. Obtain simultaneously recorded time series of local activity. Determine a significance threshold thr for local activity and obtain time and amplitude of suprathreshold peak events. The threshold thr is often estimated in multiples of the standard deviation of the signal fluctuation individually calculated for each local time series. This approach normalizes against heterogeneities introduced by differences between, e.g., local sensors/electrodes.

Step 2. Identify spatiotemporal activity clusters. Choose a temporal resolution Δt at which suprathreshold events from Step 1 will be binarized. Concatenate successive time bins of length Δt that contain at least one local suprathreshold event. The resolution Δt is often estimated by the average inter-event interval in the system, IEI , (not of the local time series). This IEI quantifies how much time passes between successive events in the system. It typically depends on the speed of activity propagation, v , and the spatial sampling distance Δd of the sampling grid (e.g., electrode array, subsampled neuronal population in 2-photon imaging, or spatial resolution in MEG or fMRI). In general, if v is constant, then $\Delta t = \Delta d/v$ at which $\alpha = 3/2$. Such rescaling was demonstrated experimentally for neuronal avalanches (Beggs and Plenz 2003; Pasquale et al. 2008).

The concatenation of successive time bins provides an unbiased cluster detection mechanism. Clusters that consist of a single time bin with just one local event reflect local, non-propagated activity. Clusters consisting of a single time bin with multiple local events capture synchronous – within resolution Δt – distant events. Clusters that consist of several consecutive time bins each with one local event represent ideal, unbranched cascading activity. Clusters with multiple consecutive time bins and numerous local events reflect intermediate realizations between instantaneous synchronization and idealized cascades. Importantly, the criterion that clusters end when the concatenation encounters a time bin with no local event establishes an unbiased

estimator for periods with and without activity. An alternative approach that does not rely on a temporal resolution is to add local events, e.g., spikes from all neurons, and threshold the resulting population vector (Poil et al. 2012; Del Papa et al. 2017) to obtain activity periods

with corresponding number of active local events foregoing any spatial resolution of clustered activity.

Step 3. *Compute statistics of clusters.* The two most commonly examined cluster parameters are cluster size s and cluster lifetime t . For a

Neuronal Avalanches, Fig. 1 Neuronal avalanche analysis. (a) Sketch of macaque brain with microelectrode array locations (square in premotor cortex). CS: central sulcus; PS: principal sulcus. (b) An example trace of an LFP signal, showing the detection of negative LFP deflections crossing threshold (marked by asterisks) at 2.5 SD (dashed line). (c) Raster plot of local events detected from all 91 electrodes in a period of 2 s. Local suprathreshold events are represented by individual dots in the plot. (d) Local events occurring during either the same or consecutive time bins are detected as a spatiotemporal cluster with size, s , defined as the number of events involved. (e) Avalanche size distributions are plotted in double-logarithmic coordinates for four observation windows,

i.e., groups of electrodes in the recording array. The size of the observation window, N , is defined as the number of electrodes within the window (see inset for spatial coverage of the windows). The positions of arrows indicate the values of the corresponding N . (f) Continuous avalanche size distributions are plotted for the same observation windows with the size of an avalanche defined as the summated absolute amplitudes of all local events involved. The positions of arrows indicate the values of N times mean absolute events amplitude across all electrodes. For visual comparison, a power law with exponent -1.5 is shown in e and f (dashed lines). (Modified from Yu et al. 2014. <https://doi.org/10.1371/journal.pone.0099761.g001>)

continuous time series such as the LFP or spike density, cluster size s can be expressed as the number of suprathreshold events, the sum of event peak amplitudes or summed area of suprathreshold event. Typically, differential sensitivities in local site measures are removed by adequate normalization (e.g., z-scoring to remove electrode differences in LFP recordings or heterogeneities in fluorescence marker expression in 2-photon imaging) and thus either size definition will give similar results for the corresponding distributions of s (see, e.g., Beggs and Plenz 2003; Plenz 2012; Bellay et al. 2015). The lifetime t is typically expressed in number of time bins of length Δt , also called number of generations. If expressed in absolute time, the number of generations is multiplied by Δt .

Step 4. *Generate probability distribution of cluster parameters such as size and lifetime.* Plot the histogram of s and of t and normalize to obtain corresponding probability density functions. Given the potential scale-invariant outcome, histograms should be obtained with logarithmic binning if possible and visualized in double-logarithmic plots. If the resulting size and lifetime distribution are power laws, these plots will appear as straight lines and the dataset has passed the first test for neuronal avalanches.

Step 5. *Quantitatively assess how close the distribution is to a power law.* There are two important aspects to take into account, when estimating size and lifetime distributions. First, as is to be expected for any scale-invariant dynamics, finite-size sampling of clusters will impose cut-offs on size as well as duration distributions (see, e.g., Priesemann et al. 2009; Klaus et al. 2011; Yu et al. 2014; Levina and Priesemann 2017). In the presence of a clear lower or upper cut-off, the use of cumulative distributions is discouraged. Cumulative distributions are heavily distorted by cut-offs particularly when only few orders of magnitudes are covered in parameter space (Yu et al. 2014). In general, it is advised to use a scaling approach to test for the robustness of the distribution and to identify distortions from subsampling (Priesemann et al. 2009; Ribeiro

et al. 2010, 2014; Levina and Priesemann 2017) as well as cut-offs introduced by finite-size effects. For example Beggs and Plenz (2003), Pasquale et al. (2008), Priesemann et al. (2009), and Yu et al. (2014) explored the systematic shift in cut-off with electrode array size and Bellay et al. (2015) normalized for the effect of neuronal population size in 2-photon imaging. After properly identifying cut-offs and subsampling effects, several approaches can be used to test for the presence of a power against alternative distributions (see, e.g., Clauset et al. 2009; Yu et al. 2014). The deviation from a true power law can be quantified (e.g., Shew et al. 2009; Tetzlaff et al. 2010), which is particularly desirable when comparing a system's change in cluster statistics due to pharmacological manipulation or during development. For a thorough analysis, distribution dependencies on threshold thr as well as Δt or Δd are encouraged. For example, the slope of the power law for sizes, α , changes systematically with Δt and can be collapsed accordingly (Beggs and Plenz 2003; Petermann et al. 2009). Similarly, it is advisable that distributions are shown to be robust to threshold thr used in the analysis within a reasonable range, i.e., above noise and within a range to obtain sufficient suprathreshold local events (Petermann et al. 2009). If used with respect to external events, proper use of Δt and thr allows for analyzing cluster distribution during behaviorally relevant periods (Yu et al. 2017). Given the dependence of slope distributions on the three parameter Δt , Δd , and thr , the exact identification of critical exponents can be challenging for limited data sets.

Step 6. *Quantitatively assess scaling between cluster size and lifetime.* Cluster lifetime and cluster size have been shown to be connected by the avalanche shape with a scaling relationship (Sethna et al. 2001; Papanikolaou et al. 2011). Specifically, the average size $\langle s \rangle$ versus lifetime t has been shown to follow a scaling relationship with exponent $\gamma = \beta - 1/\alpha - 1$. For a critical branching process that describes avalanche unfolding, $\gamma = 2 = 2 - 1/1.5 - 1$ and the avalanche waveform is a parabola. For comparison, an unbiased random walk with

$\alpha = 4/3$ - and $\beta = 3/2$ exhibits $\gamma = 1.5$ (di Santo et al. 2017). For experimental data, the calculation of γ and avalanche waveform has been used as further evidence that neuronal avalanches indicate critical dynamics in cortex (Friedman et al. 2012).

Open Questions and Future Research

Neuronal avalanches represent a statistical description of fluctuations in neuronal activity. The relationship between scale-invariant neuronal statistics and the underlying dynamics is currently an intense area of research. In human ECoG, avalanche statistics corresponds to critical eigenmodes of an autoregression matrix of order 1 that approximates the near temporal evolution of time series (Solovey et al. 2012). The relationship of the largest eigenvalue of connectivity matrices being critical and the emergence of avalanche statistics has been explored by Larremore et al. (2012). Commonly, scale-invariance is found in balanced processes such as the return times in an unbiased random walk. Accordingly, neural models with inherently balanced propagation can produce scale-invariant outcomes in many ways. Recently, the notion of “causal avalanches” was introduced, where the synaptic, i.e., causal, contribution to avalanching is tracked in neural models (Martinello et al. 2017). Causal avalanches provide an answer to avalanche statistics obtained in models that exhibit a first-order phase transition (Millman et al. 2010), but these models do not produce power law statistics when avalanches are based on temporal proximity as is found in experiments. Besides power law statistics and branching ratio, experimentally determined neuronal avalanches exhibit numerous additional features that are challenging to model. Neuronal avalanches co-emerge with brain oscillations (Gireesh and Plenz 2008), captured in some models (Poil et al. 2012; di Santo et al. 2018). The temporal organization of neuronal avalanches shows distinct conditional dependencies on avalanche size and inter-avalanche intervals (Lombardi et al. 2012, 2014, 2016; Plenz 2012), which are sensitive to the excitation/inhibition balance and for which current models do not account. Similarly, the spatial spread of avalanches in cortical slice cultures obeys a fractal dimension lower

than 2 (Plenz 2012), and its relation to the topology of the underlying neuronal network is unknown. In light of neuronal avalanches and their potential advantages for information processing (see “History of Neuronal Avalanches”), the relationship between neuronal avalanches, criticality, and synaptic plasticity is an extremely active area of research (e.g., Bornholdt and Rohl 2003; Levina et al. 2007; Meisel and Gross 2009; de Arcangelis and Herrmann 2010; Rybarsch and Bornholdt 2014b; Berger et al. 2017; Del Papa et al. 2017; Hernandez-Urbina and Herrmann 2017; Michiels van Kessenich et al. 2018).

Acknowledgments This research was supported by the Intramural Research Program of the NIMH ZIAMH002797 (Plenz) and by National Science Foundation CRCNS grant #1308174 (Shew) and by Arkansas Biosciences Institute grants 0055 and 0070 (Shew). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Neuronal Model Databases

Cengiz Günay

Department of Biology, Emory University,
Atlanta, GA, USA

Synonyms

Brute-force model databases; Neuronal parameter-measure model databases; Neuronal simulation databases

Definition

A *neuronal model database*, in contrast to neuronal databases that collect experimental data, holds instances of computational models of one type. This model can be of a single neuron or a neuronal network, which is replicated by varying its input model parameters to yield many instances that are inserted into a searchable database. Each entry in the database corresponds to one model instance, which contains: (1) values of the varied parameters (e.g., maximal conductance, reversal potential, synaptic weights) required to uniquely identify and sufficient to re-simulate the model; and (2) several key output characteristics from the model simulation (e.g., firing rate for a single neuron or a bursting period in a network). The resulting database is often used to study the relevant properties (response to stimulus or firing activity characteristics) of the model across a domain of parameter ranges.

Detailed Description

The Need for Neuronal Model Databases

In neuronal parameter space exploration, the traditional method for finding neuronal models that fit specific criteria is called *hand-tuning*, which is labor intensive, subjective and aims to optimize model parameters to a single solution (DeSchutter and Bower 1994). Furthermore, it is known that a single model may not explain all possible solutions in the parameter space because of the

interdependencies between model parameters (Foster et al. 1993; DeSchutter and Bower 1994). A better approach is to conduct systematic searches in the parameter space; and early attempts (Bhalla and Bower 1993; Goldman et al. 2001) have been used to optimize models to a predefined outcome. To make extensive systematic searches a more general tool, Prinz et al. (2003) proposed constructing neuronal model databases with sufficient information such that they can be used to answer subsequent questions about the same model (Hudson and Prinz 2010; Soofi et al. 2012). Prinz et al. (2003) also showed that multiple models with disparate parameter values can be found which exhibit similar output activity (such as response properties or firing characteristics).

Finding a group of models, rather than a single solution, that fit response criteria has been known to be a more robust in optimization problems. In machine learning, a set of algorithms called *ensemble learning* does exactly this to improve on generalization capabilities of solutions found (Opitz and Maclin 1997). Therefore, when applied to finding neuronal models, the approach is sometimes called *ensemble modeling* (Prinz 2010).

Brute-force Neuronal Model Databases

The most common type of model database is constructed using the *brute-force* approach (Table 1). This approach covers the parameter space with models for each possible combination of discrete parameter values selected from within a range (Prinz et al. 2003, 2004; Calin-Jageman et al. 2007; Günay et al. 2008; Doloc-Mihu and Calabrese 2011; Marin et al. 2013). The result is a coarse grid structure in a multidimensional space.

The model database constructed by Prinz et al. (2003) contained about 1.7 million single-compartment, conductance-based models of a lobster stomatogastric neuron. A parameter space of eight dimensions was explored by varying each maximal conductance density to have six distinct values between 0 and a conductance-specific maximum at equal intervals. The database included electrophysiological measurements for each model, such as spontaneous activity type (e.g., silent, tonic, bursting), firing times, and

Neuronal Model Databases, Table 1 Comparison of neuronal databases (*DBs*). *STG* stomatogastric, *CPG* central pattern generator, *MS* microsoft (Redmond, WA), *GP* globus pallidus, *wrkstns* workstations

additional voltage extrema information. This database was used for a thorough analysis of conductance effects on firing activity types and yielded important information like percentages of neuron models in this parameter space that were silent or firing tonically.

Prinz et al. (2004) extended the same model to construct a database of a network of three representative pyloric neurons of the lobster stomatogastric ganglion. The network model was simulated about 20 million times, while varying seven synaptic weights to five different levels, as well as five or six different versions of the three neurons in the network. Analysis of the network model database showed that similar network activity can be obtained from disparate parameters of individual model neurons and synaptic connections. An extended version of the network model database was later constructed to include about 300 activity sensor measurements in each neuron (Günay and Prinz 2010). The network sensor database was analyzed with a machine learning method (Günay and Prinz 2009), which resulted in finding the optimal parameters of neuron-localized activity sensors that would be useful for maintaining stable network activity.

Adoption of Neuronal Model Databases by Others

To our knowledge, several other groups also adopted the brute-force model database approach.

Calin-Jageman et al. (2007) applied it to study the Tritonia escape swim by constructing a database of about two million motor central pattern generator neuron network models. The neuron models were constructed using a hybrid integrate-and-fire scheme, showing that the approach can easily be applied to simpler neuronal models. Günay et al. (2008) applied the brute-force approach to study a vertebrate system by modeling neurons of the globus pallidus in the rat. About 100,000 multi-compartmental conductance-based models were simulated with five different current injection stimuli, which resulted in a database of about 500,000 items. Doloc-Mihu and Calabrese (2011) simulated 10.5 million instances of a leech heart half-center oscillator (HCO) circuit conductance-based model to construct a database that they used to categorize and analyze different activity types. This study focused on HCO model bursting activity characteristics such as period and burst regularity to analyze the instances' robustness in the parameter space. This database is important because it was later used to create another database that combines simulations with analysis of model bifurcation structure (Marin et al. 2013). Most recently, Williams et al. (2013) used a hybrid experimental and computational approach to study animal-to-animal variability in the phasing of the crustacean cardiac motor pattern. They simulated about 15,000 Morris-Lecar models of cardiac ganglion cells. Adoption of the brute-force model database approach by all of these studies shows that it

continues to be a useful tool in computational modeling of neurons and networks.

Database Storage and Other Technical Details

The techniques used for the construction of neuron model databases varied among the studies reviewed above. In particular, different researchers have personal preferences for simulation language, environment, and target hardware (see Table 1). However, it is relevant to discuss some techniques, such as the ones used for storage and access of database content. Prinz et al. (2003) and several other following studies did not save complete simulation traces and instead saved a few critical measurements, which allowed simulation and storage of a large number of models. However, this meant that simulations had to be analyzed online and could only be repeated later individually. The resulting database by Prinz et al. (2003) was stored in ASCII encoded files split into smaller pieces. ASCII files are often preferred for saving simulation output because of the simplicity of viewing and analyzing the results with existing software. Furthermore, partial recovery of corrupted ASCII files is possible, although parsing and extracting information from them is inefficient and they occupy a large amount of space. Another disadvantage is that querying the database requires writing custom programs. In contrast, binary formats (e.g., binary files and SQL databases) come with efficient querying systems (e.g., SQL language) and offer more efficient storage and faster indexed access (e.g., through hash maps). However, they can only be viewed through special software and partial recovery may be more difficult in the case of corruption.

Günay et al. (2008) stored and analyzed the database in MATLAB (MathWorks Inc, Natick, MA), using a toolbox specifically developed for model database analysis, named as Pandora (Günay et al. 2009). The approach taken with Pandora was different because of (1) its offline analysis of previously simulated output files, which provided greater flexibility in designing analysis routines to handle unexpected simulation outcomes and (2) the detailed information

extracted about action potential characteristics. However, the MATLAB environment places a limit on memory items and requires purchasing a license.

Formal database management systems (DBMS) can overcome memory limitations and are available free of charge (e.g., MySQL, Oracle Corp). In Günay and Prinz (2010), the saved information was similar to that of Prinz et al. (2004), but it resulted in too many measurements (about seven billion sensors) to be saved in ASCII format as in the previous versions of the databases. Using the MySQL tool for the network sensor database provided easy access in the standard and powerful structured query language (SQL), including a web interface for browsing and high-performing indexing optimizations for data queries. Doloc-Mihu and Calabrese (2011) also used MySQL to maintain the database of results by first saving intermediate simulation results in ASCII format and then analyzed them offline with custom Java (Oracle Corp.) programs.

Most of these studies used high-performance computing clusters to run the simulations, with the notable exception of Calin-Jageman et al. (2007), who took advantage of free times of workstations in school laboratories by creating a special version of the neuron simulator called NeuronPM (Calin-Jageman and Katz 2006).

Limitations, Alternatives, and Future Directions

There are some major limitations to constructing model neuronal databases with a brute-force approach. First, a uniform coverage of the parameter space is expensive; i.e., the number of models grows exponentially with added grid points and parameters. Therefore, brute force searches are often employed as coarse grid exploratory searches to help with further fine tuning into more interesting regions of the parameter space. Second, uniformity of parameter space coverage may be both wasteful and nonbiological. Because activity types of neuronal models are distributed nonlinearly across the parameter space, Nowotny et al. (2007) suggested that the ratios of activity types in this space may not properly reflect the

ratios in living systems. The multidimensional grid constructed by brute force methods is an unnatural representation of the parameter space and may not directly correspond to a sampling of living neurons, which were found to have some parameter constraints (such as conductance coregulations). One solution to this would be to scan the parameter space using random sampling (Ball et al. 2010). Both of these limitations are specific to the brute-force method and not about neuronal model databases themselves.

For parameter search, there are two main alternatives to the brute-force method: parameter optimization and bifurcation analysis. Both of these methods are still compatible with the idea of maintaining a database of the models found. The first alternative is employing an optimization algorithm to find models that match a specific criterion. One such popular optimization approach uses *genetic algorithms*, which are employed by Neurofitter and by multi-objective evolutionary algorithms for finding a set of good neuronal models. Optimization methods explore more fine-grained values of parameters than the brute force method; however, they are not guaranteed to provide complete coverage of the space. Therefore, if a database is constructed, it would not contain a general solution and would only be useful for the criterion selected.

A second alternative approach that still gives a general overview of the parameter space is bifurcation or phase-plane analysis of dynamical systems (Strogatz 2006). These methods can track regions of parameter space that exhibit physiological activity types without wasting resources scanning uninteresting parts of the parameter space. Therefore, they are efficient and thorough. However, bifurcation analysis requires tracking few parameters at the same time, so it is more difficult for being systemically applied to a space with a large number of parameters. Further developments in these methods would be extremely valuable for parameter search and constructing neuronal model databases that can answer general questions. In one such recent study, strengths of bifurcation and brute-force database approaches were combined (Marin et al. 2013); such an approach could become the next frontier in this field.

Neuronal Model Hand-Tuning

Victoria Booth

Synonyms

Manual parameter tuning

Definition

In all mathematical models of neuronal systems, there will be a number of parameters whose values have not been determined by experimental studies. Appropriate values for these parameters must then be determined for the model to replicate the desired experimental behavior or to exhibit the desired dynamics. Hand-tuning is the process of manually adjusting parameter values, simulating the model and determining if the adjustments result in the desired model behavior. This method contrasts with automated parameter optimization algorithms in which parameter values to be tested and determination of model fitness are computed by an optimization algorithm.

Detailed Description

In developing a neuronal model, some amount of parameter hand-tuning is unavoidable. Even if an automated parameter optimization algorithm is to be used, hand-tuning may initially be necessary to identify ranges of parameter values to search over or to identify preliminary estimates of model sensitivity to parameters for determining which parameters to vary in an automated optimization. However, in some cases, hand-tuning to identify optimal parameter values may be a preferred or unavoidable method.

An immediate advantage of hand-tuning is its ease: no additional coding or development of a fitness measure is necessary. The modeler sets

parameter values for the model, simulates the model, and observes the model behavior, requiring no further computational resources than those needed to implement a single model simulation run. However, hand-tuning has a number of significant disadvantages as has been discussed elsewhere (Prinz 2007). It is extremely time consuming. While some parallelization may be implemented by simulating and observing results from multiple parameter sets simultaneously, it generally is a serial process. It is difficult and potentially frustrating to understand the effects of changes in parameters on model results given the strong nonlinearities of neural models. Thus, determining appropriate parameter changes to obtain desired results can be difficult. Results of hand-tuning may be subjective in that the modeler chooses the specific parameter values to be tested and if a fitness function is not quantitatively defined, an optimal fit may be decided by only a visual test. Finally, the end result is only a single optimal parameter set which may have limited utility or relevance given the variability of behavior among neurons of the same type or the occurrence of similar model behavior with different but perhaps related parameter sets (Ball et al. 2010; Hudson and Prinz 2010).

One potential advantage of taking the effort to optimize parameters by hand-tuning is that the modeler will certainly develop a deep intuition and understanding of the model's sensitivity to parameters. By observing the effects of each change in parameters and minding how the changes relate to the desired model output, the modeler can directly gain knowledge about how model characteristics are affected by certain parameters and combinations of parameters. Thus, while developing this understanding represents a source of difficulty of parameter hand-tuning, overcoming this difficulty can lead to significant insights that can benefit the modeler and the modeling work.

Implementing parameter hand-tuning is best considered under certain conditions. The number of parameters to be varied should be small, and estimates of bounds on parameter values should be available, so that the dimension and extent of the parameter space to be searched are not too large.

The desired model output should be directly affected by the varied parameters, which is related to the identifiability of the parameters (Chis et al. 2011; Little et al. 2010). For example, if the desired model output is a particular profile of a frequency-current curve or of action potential afterhyperpolarization, hand-tuning is easier if the varied parameters directly affect firing frequency or the time course of membrane repolarization, respectively. Hand-tuning is much more difficult if the desired model output involves higher-order properties of neural behavior that depend on the action or interaction of multiple parameters (Li and Vu 2013). Additionally, hand-tuning may be a preferred option when the desired model output needs to only display certain qualitative features, rather than fit specific, quantitatively characterized behaviors or experimental data. In this case, defining a fitness function for an automated parameter optimization algorithm may be more challenging than parameter hand-tuning.

Despite its limitations and disadvantages, several studies have implemented parameter hand-tuning successfully in complex neural models, including multi-compartment models of single cells (Booth et al. 1997), and small networks of synaptically coupled neurons (Nadim et al. 1995) and electrically coupled neurons (Soto-Trevino et al. 2005).

Objective; distance; error; cost; or match functions in neuronal model optimization

Definition

A fitness function is a procedure, typically analytical, which quantifies the degree to which a data set or solution meets a given goal. In neuronal modeling, fitness functions typically compare the result of a computer simulation against biological activity for the purpose of guiding parameter optimization.

Detailed Description

Background

Computational models are widely used in neuroscience. These models vary greatly in the level of

biological verisimilitude. At one extreme are detailed conductance-based compartment models that model neuron conductances with physiologically derived differential equations, appropriately distributed on accurately reproduced neuron anatomies (Skinner 2006). At the other extreme are highly abstract models with greatly simplified individual neurons and synapses, e.g., integrate and fire neurons with simple on/off synapses. All such models have free parameters which must be fit before the model faithfully reproduces the biological activity of the system of interest. In some cases, it is possible to experimentally measure neuronal parameter values, such as maximal conductance values and passive membrane properties. However, this typically requires many experiments, and these parameters often vary across similarly behaving neurons. The resulting models typically require hand-tuning of parameter values, a time-consuming and difficult process, before the desired activity is reproduced.

An alternative approach is to fit the model by adjusting its parameter values until a desired activity is obtained. When the model is very simple, or where the goal is to reproduce only the most general features of activity (e.g., the neuron fires action potentials upon depolarization), it may be possible to hand-tune, or to exhaustively survey all possible parameter values (the *search space* or *parameter space* of the model). For most models, however, this is impossible, due to the large number of free parameters, the resolution at which the parameter space must be explored, and the computational time required. Instead, parameter fitting is automated using algorithms which adjust the parameter values until the desired target output is achieved. Intrinsic to this process is the use of an *objective function* to quantitatively compare the activity of the model against the target biological activity. Many such functions have been used. They are properly called *fitness functions*, when they yield high values for similar activity, or *distance functions* or *error functions* when they yield low values for similar activity. It is common however in computational neuroscience to refer to any objective function used in optimization as a fitness function, and we will continue this usage below.

Note that there is no inherent requirement that fitness function output will vary in a way that can be used to direct parameter optimization. For instance, consider a distance function that gave a distance of zero (identical output, i.e., good fitness) only for a narrow range of parameter values for which the model's activity closely reproduces the target, and one (poor fitness) otherwise. Though valid, such a measure would have very limited utility. Even when a model has only a few parameters, model output may change abruptly with small changes in parameter values. Finding the right set of parameter values may therefore require an unfeasibly fine-grained search to escape the plateau of poor fitness. A good fitness function is responsive to changes in model activity throughout the parameter space, so that fitness changes can drive the optimization process towards the desired activity, ideally with a strong gradient and few plateaus or local minima. An additional concern is that nearly identical spontaneous activity can be produced with widely different sets of parameter values, both in conductance-based neuronal models (Prinz et al. 2004; Achard and De Schutter 2006) and in actual neurons (Schulz et al. 2006). Model parameter fitting may therefore require a means to perturb the activity of the model and the target neuron, to provide additional information which may help separate otherwise identically behaving neurons. We cover this aspect of model parameter fitting, and how it relates to the choice of fitness functions, in a final section below.

To illustrate the use of fitness functions, the Morris-Lecar conductance model of giant barnacle muscle fibers (Morris and Lecar 1981; Ellner and Guckenheimer 2006) is used herein. This model includes a calcium conductance, delayed rectifier, and leak conductance, governed by the following system of equations:

$$C \frac{dV}{dt} = -g_{Ca} M_{SS} (V - V_{Ca}) - g_K N (V - V_K) - g_L (V - V_L)$$

$$\frac{dN}{dt} = \frac{N - N_{SS}}{\tau_N}$$

where M_{SS} and N_{SS} , the steady-state activation values, are

$$M_{SS} = \frac{1}{2} \left(1 + \tanh \frac{V - V_1}{V_2} \right)$$

$$N_{SS} = \frac{1}{2} \left(1 + \tanh \frac{V - V_3}{V_4} \right)$$

and the time constant is

$$\tau_N = \tau_0 \operatorname{sech} \frac{V - V_3}{2V_4}$$

The maximal conductance values, reversal potentials, slope and half-maximal activation voltages, and base time constant are the free parameters of the model. Depending on their values, the Morris-Lecar model can produce a variety of intrinsic activity.

Fitness Functions and Model Parameter Optimization

In neuronal modeling, objective or fitness functions measure the similarity between the activity of a neuron and that of a neuronal model. These functions express this difference as a scalar value. In optimization, this value is minimized (error, distance, or cost functions) or maximized (fitness functions proper). As a trivial example, if the goal were to obtain a neuronal model having a particular resting membrane potential (V_{rest}), the absolute value difference between the V_{rest} of the model and the desired resting potential could be used as a distance measure. The optimization process would explore various parameter values, and this distance measure would drive the optimization process to choose parameter values whose models' resting potentials were increasingly closer to the target.

A fitness function evaluated over the set of all possible model parameter values produces a *fitness landscape*. This can be visualized intuitively as a physical landscape, where the height – the fitness of the model's output compared to the

target activity – varies as a function of surface location, i.e., the parameter values of that model. As traditionally defined, better fitness is indicated by greater absolute fitness function values. In practice, however, cost, distance, or error functions are often used, in which case better fitness is indicated by smaller error values (it is this choice that is used in Fig. 5 here). A fitness function is considered a *distance metric* if it satisfies four conditions:

- Nonnegativity: $d(a,b) \geq 0$, for all a,b
- Identity: $d(a,b) = 0$ if and only if $a = b$
- Symmetry: $d(a,b) = d(b,a)$, for all a,b
- Triangle inequality: $d(a,b) \leq d(a,x) + d(x,b)$, for all a, b , and x

Many fitness functions used in neuronal modeling fail one more of these criteria, notably the identity and the triangle inequality. For instance, the phase plane fitness distance (see below) fails the identity condition because different waveforms can give zero distance. When the goal is to produce a particular activity with high fidelity, this may be a concern. In many cases, however, the difference between the “different” waveforms is a simple phase shift, which may be irrelevant to the modeling goals. In such situations, the insensitivity of phase plane distance to phase differences is actually an advantage.

Having chosen a fitness function, the next step is optimization, using this fitness function to determine the parameter values which produce the target activity (Moles et al. 2003; Prinz 2007; Van Geit et al. 2008). This is done by evaluating the fitness associated with a particular set of parameter values and adjusting those parameter values to improve the fitness (or reduce the error) between the model’s activity and the target. When the fitness landscape gradient can be calculated, and no plateaus or local minima (high error “pockets” on the landscape where error further increases in all directions), simple gradient descent can be used to fit the parameters (Bhalla and Bower 1993). When local minima do exist, techniques such as simulated annealing (Van Geit et al. 2008) can be used to escape them. In cases

where the gradient of the fitness function is unknown, a simplex descent (Nelder and Mead 1965) will find minima if they exist, but can become trapped in plateau regions of the fitness landscape. In general, the fitness landscapes of most models and fitness functions are not suitably well behaved, and these methods do not give good results.

An alternative optimization strategy is to use heuristic approaches that incorporate elements of randomness. While not guaranteed to find the global minimum, these approaches often provide good performance in acceptable time for problems that are otherwise intractable. Evolutionary algorithms, for example, are based upon the principles of natural selection and treat the parameters of the model as a genetic code and its behavior as a phenotype (Keren et al. 2005). An initial population of individuals is created with random genotypes, and each individual’s phenotypic fitness is evaluated. Then, during each generation, individuals compete, the population is reduced by survival of the fittest, survivors may recombine by exchanging or otherwise transforming parameters, and mutated offspring are generated. With each successive generation, the fitness of the population improves. Swarm optimizers are based upon the behaviors of social organisms (Hanrahan 2011), such as bees, ants (Dorigo et al. 1999), or even cats (Saha et al. 2013), and move a population of candidate solutions within the parameter space using rules governing their individual and collective position and velocity. A further sophistication is the use of metaheuristic optimization methods (Osman and Laporte 1996), in which different heuristic approaches are sequentially used either randomly or in response to population characteristics reaching set trigger values.

Unfortunately, in general, there is no way to know a priori which optimization approach will work best, and for any approach, there may be fitness landscapes which can give poor results. Since fitness landscapes depend in part on fitness function, it also follows that which optimization approach will work best depends on the fitness function chosen. Identifying which fitness

functions and optimization procedures will give good results inevitably involves a degree of trial and error. Another difficulty is that a particular fitness function and optimization procedure may perform well for some parameters but not others. It is thus sometimes desirable to incorporate multiple fitness functions by weighted summation or by changing fitness functions with successive generations.

Fitness Functions

The selection or design of appropriate fitness functions depends on many factors, most notably how similarity is assessed and what features are important to replicate. If the goal is to reproduce a spike train, for example, a fitness function which is sensitive to activity below spiking threshold, but relatively insensitive to spike timing or count, is a poor choice. On the other hand, such a fitness function could be a good choice for adjusting the conductance parameters of a slow-wave oscillator. Too many fitness and distance functions have been used in neuronal modeling to exhaustively survey all of them. We instead cover below only the more common ones. These may provide adequate performance for a given modeling task or can be used as starting points for designing ad hoc functions. In general, neuronal modeling fitness functions can be grouped by whether they primarily assess continuous activity, discrete activity (spike trains), or both.

Continuous Activity Fitness Functions

Continuous activity fitness functions quantify the difference between two continuous waveform traces or time series, a and b . Without loss of generality, these will be assumed to be continuous functions, though in practice these are typically time series obtained by regular sampling of neuronal activity and matched resampling of model output. Also, the two waveform traces are assumed to be of equal duration, t_{tot} , as it is common to simulate model response to match the duration of the target.

Waveform Distance

The simplest fitness function is waveform distance, D_w , which directly compares two waveforms of equal length t_{tot} :

$$D_w = \frac{1}{t_{\text{tot}}} \left(\int_{t=0}^{t_{\text{tot}}} |a(t) - b(t)|^p dt \right)^{1/p}$$

With $p = 1$ (Manhattan distance), this function measures the mean absolute difference between the waveforms (Fig. 1a); more commonly the Euclidean distance, $p = 2$, is used. Assuming t_{tot} is held constant throughout the optimization, D_w with $p = 2$ is the familiar root mean squared error measure (Bhalla and Bower 1993):

$$D_{\text{RMS}} = \sqrt{\frac{1}{t_{\text{tot}}} \int |a(t) - b(t)|^2 dt}$$

Waveform distance satisfies the criteria required to be a distance metric, provided the $1/p$ exponent is maintained in the D_w equation. It is, however, highly sensitive to phase differences between the waveforms, yielding increasingly large error measures as otherwise identical waveforms become increasingly out of phase. This difficulty can be overcome by entraining the neuron and model with an appropriate stimulation (e.g., a current pulse), or by calculating waveform distance as a function of time offset, analogous to cross-correlation (see below),

$$D_w(\tau) = \frac{1}{t_{\text{tot}}} \left(\int |a(t + \tau) - b(t)|^p dt \right)^{1/p}$$

and then taking the minimum such $D_w(\tau)$ as the scalar distance value. Where resting potential or amplitude is irrelevant to the modeling goals, the waveforms can be normalized by mean and/or variance prior to computation of waveform distance. With long periodic samples (Fig. 1b), waveform distance becomes highly sensitive to slight cycle frequency differences, producing pathological fitness landscapes with large plateaus

Neuronal Model Output Fitness Function,

Fig. 1 Waveform distance (D_W) calculation between two Morris-Lecar model membrane voltage traces. Waveform distance is a commonly used simple fitness function when fitting non-spiking neuronal models. In its simplest form, it measures the mean difference between two waveform traces (a). It is highly sensitive to phase differences (see text) or with long samples of periodic waveforms, even slight frequency differences (b), which can overwhelm the contribution of differences of other characteristics such as amplitude or waveform shape

of high error which increase in the immediate neighborhood of the target. Due to the relatively short duration of the spikes compared to typical waveform samples, waveform distance is relatively insensitive to differences in spike count or timing.

Phase Plane Distance

Another method to avoid the phase sensitivity of waveform distance is to use *phase plane distance*, D_{ph} , which, loosely, calculates the overlap of the two waveforms in a two-dimensional half-phase plane, e.g., $(dV/dt, V)$ for voltage traces (LeMasson and Maex 2001). This measure bins each waveform into a two-dimensional density matrix M of suitable size and resolution and then measures the differences between bin counts (Fig. 2):

$$D_{ph} = \left(\sum_i \sum_j \left| \frac{M_a(i,j)}{N_a} - \frac{M_b(i,j)}{N_b} \right|^p \right)^{1/p}$$

where N_a and N_b are the number of samples. Because difference is only measured within bins, a miss (two samples falling in adjacent bins) is as good as a mile (the same two samples in widely separated bins). Matrix extents and resolution can thus strongly affect the performance of the metric. Too coarse a grid will be insensitive to small differences, notably in spiking activity. Too fine a grid will detect such features, but dissimilar waveforms will give errors which fail to decrease appreciably until the waveforms become very similar, resulting in plateaus on the fitness landscape.

Linear Synchrony Measures

Linear synchrony measures (Kreuz 2013) can be used as fitness functions. The cross-correlation between two waveform traces is one such commonly used measure:

$$C(\tau) = \int_{t=k}^{t_{tot}-k} \hat{a}(i+\tau) \hat{b}(i) dt$$

Neuronal Model Output Fitness Function, Fig. 2 Phase plane distance (D_{ph}) calculation between two Morris-Lecar model voltage traces. Phase plane distance bins regularly sampled response waveforms (see Fig. 1) into a density matrix in the half-phase plane (e.g.,

dV/dt vs. V for a membrane potential recording). The mean pairwise difference between bin counts yields the distance between the two traces. Phase plane distance is insensitive to waveform phase differences

where $\hat{a}$ and $\hat{b}$ are the waveforms normalized to zero mean and unity variance, and $-k < \tau < k$ is constrained so as to provide overlap between the two waveform traces over the range in which cross-correlation is evaluated. $C(\tau)$ ranges from 1 for complete correlation, through 0 for independent waveforms, to -1 for complete anti-correlation. Thus, the maximum $|C(\tau)|$ over all τ can be used to measure the phase-independent similarity between the two waveforms. Note this value should be maximized, not minimized, by the optimizer.

Discrete Activity Fitness Functions

In many neuronal models, it is assumed that information is coded primarily in the timing and rate of action potentials and that the slow-wave activity of the neuron and amplitude and shape of the action potentials are irrelevant. In such models, fitness functions which consider only spike timing are used. Many such measures exist (Victor 2005; Kreuz et al. 2007; Victor and Purpura 2010; Kreuz 2011; Houghton and Victor 2012). These take, as input, a discrete time series comprising the times of the action potentials in the spike train and calculate distance from differences in features such as the spike count, timing, or interspike interval (Fig. 3).

Spike Count, Spike Time, and Interspike Interval Distances

Spike count (D_{SC}), spike time distance (D_{ST}), and interspike interval distance (D_{IS}) are relatively simple measures:

$$D_{SC} = |N_a - N_b|$$

$$D_{ST} = \frac{1}{N} \left(\sum_{i=1}^N |t_a(i) - t_b(i)|^p \right)^{1/p}$$

$$D_{IS} = \frac{1}{N-1} \left(\sum_{i=1}^{N-1} |d_a(i) - d_b(i)|^p \right)^{1/p}$$

where N_a and N_b are the number of spikes in a and b , $N = \max(N_a, N_b)$, $t(i)$ is the time of the i th spike, and $d(i) = t(i+1) - t(i)$ is the interspike interval time. D_{ST} measures the degree of coincidence between the two spike trains and is thus sensitive to phase differences, whereas D_{IS} is insensitive to phase. D_{ST} and D_{IS} are both sensitive to missing spikes in either or both spike trains, which can be a concern when attempting to model real neuron recordings.

Neuronal Model Output Fitness Function, Fig. 3 Spike train measures used in some spike timing-based fitness functions. Many fitness functions used to

quantify difference between spike trains rely upon basic features such as the timing of the spikes (t), the interspike interval (d), or the mean of paired interspike intervals (m)

Spike Time Alignment and Interval Alignment Distances

The spike time alignment distance (Victor and Purpura 1996), similar to string edit distance, measures the minimum total cost required to transform one spike sequence into another by inserting, removing, or moving spikes (Fig. 4). Insertion or removal of a spike are both assigned cost of 1, and changing the time of a spike by Δt is assigned a cost of $q\Delta t$, where q is a tuning parameter of the function. For $q = 0$, spike time alignment distance measures differences in spike count. For small values of q , the function is more sensitive to differences in spike rate than spike timing. For larger values of q , spike time alignment distance becomes comparable to D_{ST} but with less sensitivity to missing spikes. For very large values of q , however, the algorithm removes and reinserts spikes rather than moving them, which can be overcome by using unequal insertion and deletion costs. The interval alignment distance is analogous, measuring the cost to change interspike intervals, $q\Delta d$.

Kernel Methods

An alternative approach with discrete data is to convolve the spike trains with a suitable kernel to transform them into continuous functions and then use measures suitable for continuous time series (Fig. 5). The van Rossum distance (van Rossum 2001; Fig. 5, left column) convolves each spike train with a half-exponential kernel:

$$k_{vR}(t) = \begin{cases} e^{-t/\tau} & t \geq 0 \\ 0 & t < 0 \end{cases}$$

to produce continuous waveform traces and then calculates mean square difference of the convolved waveforms:

$$D_{vR} = \frac{1}{\tau} \int_{-\infty}^{\infty} [(a * k_{vR})(t) - (b * k_{vR})(t)]^2 dt$$

When τ is small, the van Rossum distance is sensitive to spike coincidence, as the convolved

Neuronal Model Output Fitness Function,

Fig. 4 Spike time alignment distance. The spike time alignment distance measures the total “cost” to transform one spike train (*a*) into another (*b*). Insertion or removal of a spike has a fixed cost of 1; moving a spike by Δt has a cost of $q\Delta t$. For small values of q , the algorithm compares spike count; for larger q values, it is a coincidence detector

Neuronal Model Output Fitness Function,
Fig. 5 Kernel-based spike timing measures. Kernel approaches convolve discrete spike trains (*a*; *red*, constant frequency spike train; *blue*, spike train of decreasing frequency) with a kernel such as a half-exponential (*b*, *d*) or Gaussian (*c*, *e*) to create continuous waveform traces. Then, the difference between the continuous waveform traces is quantified using a measure such as waveform distance (*black traces*, showing time-wise square difference between *red* and *blue traces*). The temporal width of

the kernel is a tuning parameter; when this is small (*b*, *c*), these methods primarily measure spike timing coincidence (note how coincident spikes yield low area under the corresponding black traces and thus low waveform distance). With larger kernels (*d*, *e*; convolved waveform of first spike shown in *dashed blue*), these methods are more sensitive to differences in spike rate (note divergence of *red* and *blue traces* and thus *black trace* of increasing amplitude, as the frequency of the two spike trains diverges)

waveforms overlap extensively only when the spike timing is very similar (Fig. 5b). With larger τ (Fig. 5d), the function becomes a rate measure. A Gaussian kernel has also been used (Schreiber et al. 2003; Fig. 5c, e), typically with cross-correlation instead of waveform distance. As with van Rossum distance, the function's sensitivity to rate or timing depends upon kernel size.

Parameter-Free Methods

The Victor-Purpura and kernel methods rely upon a parameter to adjust the time sensitivity of the fitness function. Parameter-free alternatives are sometimes desirable, e.g., when spike frequency varies over a wide range. The parameter-free spike distance, D_{SPIKE} , is calculated as follows. First, for each spike train, three continuous functions are created. One, $t_p(t)$, is the time of the nearest previous spike, or the beginning of the recording if before the first spike. The second, $t_f(t)$, is the time to the nearest next spike, or the end of the recording if after the last spike. The final, $w(t)$, is the width of the interspike interval between these two:

$$t_p(t) = \max(t_a(i) | t_a(i) \leq t \forall i)$$

$$t_f(t) = \min(t_a(i) | t_a(i) \leq t \forall i)$$

$$W_a(t) = t_{f_a}(t) - t_{p_a}(t)$$

and similarly for the second spike train (b). The mean interspike interval is also calculated:

$$\overline{W}(t) = \frac{w_a(t) + w_b(t)}{2}$$

Next, differences across the two spike trains are calculated, by measuring the difference from t_p or t_f in one spike train to the nearest spike in the other spike train.

$$\Delta t_{p_a}(t) = \min(t_{p_a}(t) - t_b(i) \forall i)$$

$$\Delta t_{f_a}(t) = \min(t_{f_a}(t) - t_b(i) \forall i)$$

and, again, similarly for spike train b . For each spike train, a locally weighted average function is calculated:

$$S_a(t) = \frac{\Delta t_{p_a}(t)(t - t_{p_a}(t)) + \Delta t_{f_a}(t)(t_{f_a}(t) - t)}{W_a(t)}$$

and, again, similarly for $S_b(t)$. Finally, the time-varying dissimilarity profile is calculated:

$$S(t) = \frac{S_a(t)w_b(t) + S_b(t)w_a(t)}{2 - w(t)^2}$$

Integrating this over the total recording time gives the scalar D_{SPIKE} distance:

$$D_{\text{SPIKE}} = \frac{1}{t_{\text{tot}}} \int_{t=0}^{t_{\text{tot}}} S(t) dt$$

A similar parameter-free method, D_{ISI} , exists based upon interspike intervals instead of spike timing.

Hybrid and Alternative Methods

Fiducial-Point Distance

The fiducial-point distance, D_{fp} , utilizes both continuous waveform data and spike timing data. The times of matched action potentials in the two waveforms are used as “fiducial points,” i.e., fixed reference points (Ambros-Ingerson et al. 2008), to align the continuous data prior to comparing them. The times of the N_a action potentials in waveform a , $t_a(i)$, and the N_b action potentials in waveform b , $t_b(i)$, are first identified. Only the minimum of the two, $N = \min(N_a, N_b)$ are used. The interspike intervals, $d_a(i)$ and $d_b(i)$, and their mean, $m(i) = (d_a(i) + d_b(i))/2$, are calculated (see Fig. 3) for all $i \leq N$. The $N + 1$ fiducial points, $q_a(i)$ and $q_b(i)$, are calculated as follows:

$$q_a(i) = \begin{cases} 0 & i = 0 \\ t_a(i) & 0 < i < N \\ \max(t_a(N), t_b(N)) & i = N \\ t_{\text{end}} & i = N + 1 \end{cases}$$

Then, stretch factors are calculated for each waveform and for each interspike interval: $s_a(i) = d_a(i)/m(i)$ and $s_b(i) = d_b(i)/m(i)$. Finally, waveform distance is calculated using these stretch

factors to shrink or expand each section between spikes so that the spike times coincide:

$$D_{fp} = \frac{1}{t_{\text{tot}}} \left[\sum_{i=0}^N \int_{t=0}^{m_i} |a(s_a(i)t + q_a(i)) - b(s_b(i)t + q_b(i))|^p dt \right]^{1/p}$$

Mutual Information

Mutual information is the reduction in uncertainty about one variable from having knowledge of another. It is often used in neuroscience to estimate the degree to which the response of a neuron is due to its driving input, but can also be used as a nonlinear measure to compare neuron and model activity. Formally, mutual information is defined as

$$I(X; Y) = \sum_{x \in X} \sum_{y \in Y} P_{XY}(x, y) \log \frac{P_{XY}(x, y)}{P_X(x)P_Y(y)}$$

where P_{XY} is the joint probability distribution and P_X and P_Y are the marginal probability distributions. Typically, this is estimated by measuring some characteristic or feature of the data, such as spike count or timing, and then binning the data to estimate the probability distribution of this feature. Other information-based measures, such as transfer entropy, can also be applied (Gray 1990).

Feature-Based Approaches

Real neurons often produce different responses to repeated identical perturbation (Nowak et al. 1997). This can be problematic if the fitness function is overly sensitive to the noise component. An alternative approach is to isolate multiple features of interest in the voltage or current response of the neuron, such as spike rate or action potential shape (height and duration). A multiple objective optimization method is then used which compares the model's activity against the reference simultaneously in each of these features (Deb 2001). This method can produce good fits to noisy data, finding parameter values which reproduce the desired features of interest (Druckmann et al. 2007).

Driving Input

It is often desirable in neuronal modeling to reproduce a neuron's activity with the intention of obtaining insights into the neuron from the fitted parameters of the model. However, many neuronal models can produce essentially identical activity across a wide range of parameter values (Prinz et al. 2004; Achard and De Schutter 2006). As a trivial example, for many different combinations of parameter values, the Morris-Lecar model will produce identical, quiescent output, a constant resting membrane potential. However, once stimulus current is applied, the model produces periodic oscillations whose frequency and amplitude depend upon parameter values (Fig. 6a).

Even when the spontaneous activity of the model does vary with differing parameter values, a particular fitness function may not be sensitive to these differences. Again considering the Morris-Lecar model, two different parameter combinations can produce rhythmic output of the same cycle frequency but different amplitude and shape (Fig. 6b). If amplitude and shape are important features to consider in fitting the model, waveform distance with long sample duration would be a poor choice, as its very high sensitivity to frequency differences could overwhelm its response to other differences, and thus it may drive the optimizer to fit only target frequency. With appropriate perturbation, these two model neurons may begin to produce activities with different frequencies, which this fitness function could then detect.

When fitting to real neurons, where some of the membrane potential response is due to the intrinsic noise of the neuron, repeating the stimulation can be useful. Ideally, the fitness functions used to fit a model to these neurons would be relatively insensitive to variations in neuronal activity across these repeats, but sensitive to differences across neurons.

Current Clamp

Current pulses, steps, or ramps are commonly used as driving input to neuronal models or real neurons. Differences in response amplitude, slow-wave frequency, spike rate and timing, delay until first spike onset, or other features may all vary depending upon

Neuronal Model Output Fitness Function, Fig. 6 Neuronal models can produce similar activity with different parameter values. (a) Two Morris-Lecar models with different parameters but identical resting potentials respond differently to the injection of constant current (90 nA, beginning at 0.1 s). (b) Models with

different parameters can also produce output which is distinctive, but not every fitness function is sensitive to these differences. Waveform distance with long samples would measure these two waveforms as relatively similar due to their equal frequency

current amplitude or ramp slope. These can then provide useful information which can facilitate parameter fitting. A more general approach is to drive the neuron or model with noise due to the ability of noise stimulation to elicit consistent responses with high information content (Tateno and Pakdaman 2004). Such noise may include Gaussian white noise, or pink noise. Ornstein-Uhlenbeck process noise, which more closely approximates synaptic input, has also been used, notably in stochastic models (Tuckwell et al. 2002; Koutsou et al. 2013). Noise stimulation is commonly used when studying spike trains. An advantage of current clamp perturbation is that there is a closed feedback loop in which the states of the ionic conductances, which depend upon the membrane potential, in turn drive changes in that membrane potential. Thus, the responses of the neuron and model include all of the interactions and temporal dynamics of the neuron's own membrane and conductances. For instance, single, relatively simple perturbations (a current pulse) can trigger relatively long-lasting, large, self-generated responses (an action potential, a burst of action potentials). As such, provided the perturbations are of sufficient amplitude and duration to trigger conductance activation, the ability of current clamp perturbation to explore large regions of the neuron or model activity

space depends much less on the fine details of the perturbation than in voltage clamp.

Voltage Clamp

In voltage clamp, assuming no space clamp limitations, the membrane potential throughout the neuron is constrained to the command potential. It is thus impossible to drive a neuron or model through a wide range of phase space without a driving input whose characteristics match the dynamic response of the conductances. In such conditions, noise stimulations can thus be a poor choice, as the neuron spends most of its time in intermediate membrane potentials where conductances are not appreciably activated, and excursions to depolarized or hyperpolarized potentials, when they do occur, are rarely long enough to activate any but the fastest conductances. Sine or square wave chirps, or other stimulations which appreciably activate the voltage-dependent conductances and thus explore a wide range of conductance states, may be a better choice if voltage clamp is to be used. Again, absent space clamp concerns, voltage clamp can be advantageous for modeling as the absence of intrinsic activity produced by the closed feedback loop simplifies the fitness landscape, and may allow isolation of conductances with different temporal dynamics.

Neuronal Model Reduction

Richard Naud

Department of Physics, University of Ottawa,
Ottawa, ON, Canada

Definition

The act of reducing the complexity of a mathematical neuron model while preserving its essential features.

Detailed Description

The biophysical description of ion channels distributed on a three-dimensional neuron membrane is a typical example of a complex mathematical neuron model. In such models, the voltage dependence of ion channels follows the formalism of Hodgkin and Huxley. Therefore, each patch of membrane is characterized by the membrane potential, x_1 , and the state of activation/inactivation for every ion channel type, $x_2, \dots, x_n$. These state variables evolve according to a differential equation arising from biophysics and biochemistry. The equations are typically of first order in time, but nonlinear. Given the nonlinear functions $f_1, f_2, \dots, f_n$, the evolution of n state variables follows:

$$\begin{aligned}\frac{dx_1}{dt} &= f_1(x_1, x_2, \dots, x_n, y_1, y_2, \dots, y_k) \\ \frac{dx_2}{dt} &= f_2(x_1, x_2, \dots, x_n, y_1, y_2, \dots, y_k) \\ &\dots \\ \frac{dx_n}{dt} &= f_n(x_1, x_2, \dots, x_n, y_1, y_2, \dots, y_k)\end{aligned}\quad (1)$$

where $y_1, y_2, \dots, y_k$ represent k external variables, typically variables from the surrounding membrane patches. More complete models take into account intracellular and extracellular concentration of ions, neurotransmitters, neuromodulators, etc. The mathematical neuron model is obtained by combining systems of equations such as in Eq. 1 for membrane patches throughout the

neuron morphology. Overall, the equations can describe synaptic activation, ion fluxes, membrane potential dynamics, and action potential generation.

Taking a phenomenological perspective, a neuron integrates all excitatory and inhibitory input until it reaches a threshold. Once the threshold is reached, it emits an action potential and integration is reset. This integrate-and-fire model does not model the ionic concentrations or many other biophysical properties. It overlooks some dynamical features of neurons such as adaptation or dendritic spikes but can reproduce the activity of real neurons in some degrees.

In many applications, it is essential to achieve a correct mapping between synaptic input and action potential output. Simpler description can often approximate this mapping correctly. Neuronal model reduction is the process of deriving the simpler description from the complex one. For a single patch of excitable membrane such as described by Eq. 1, there are two typical approaches: dimensionality reduction of the dynamical system and the functional approach. These approaches can be used to reduce the morphologically complete description as well.

Dimensionality Reduction in Dynamical Systems

Analysis of the dynamical system may reveal state variables that covary. When this is the case, it is possible to reduce the dimensionality of the system by setting one state variable as proportional to the other. Investigating further may uncover a separation of time scale between one subsystem and another. This allows to reduce the dimensionality further. Also, the form of the nonlinearities ($f_1, f_2, \dots, f_n$) can be approximated by simpler descriptions without qualitative change in the resulting dynamics.

A classical example of neuronal model reduction of this type was reported by Fitzhugh (1961) and Nagumo et al. (1962). They performed a reduction of the Hodgkin-Huxley equation from four dimensions to two. The Fitzhugh-Nagumo equations can be written in the same formalism as Eq. 1:

$$\begin{aligned}\frac{dx_1}{dt} &= f_1(x_1, \dots, x_2, y_1) \\ \frac{dx_2}{dt} &= f_2(x_1, \dots, x_2)\end{aligned}\quad (2)$$

where x_1 is the membrane potential, x_2 is an abstract recovery variable, y_1 is the injected current, f_1 is polynomial linear in x_2 but of third order in x_1 , and f_2 is bilinear. This simple equation can describe the generation of action potential and many dynamical features of the Hodgkin-Huxley equations.

The presence of different ion channels can lead to a variety of functions f_1 and f_2 (Izhikevich 2007). The model of Morris and Lecar (1981) is another classical example. Using sigmoidal functions, they derived a reduced model of barnacle giant fibers activity.

Another approach to reduce the dimensionality of excitable systems is to introduce a threshold. The basic assumption here is that action potentials are stereotypical events. Once the threshold is reached, the state variables undergo a simple update rule. Introducing a threshold leads to a reduction of complexity because the nonlinear dynamics responsible for the action potential are replaced by a simple update rule. The Izhikevich model (Izhikevich 2003) and the adaptive exponential integrate-and-fire model (Brette and Gerstner 2005) offer a general framework for such reductions.

More general approaches for model reduction can be used. The first step in these methods involves rewriting Eq. 1 in matrix form. Then matrix decompositions such as the singular value decomposition are used. These methods are variants of proper orthogonal decomposition (Chaturantabut and Sorensen 2010), and they have been applied to the Hodgkin-Huxley equations (Kellems et al. 2010). A twofold reduction in dimensionality was achieved while preserving accurate spiking and subthreshold behavior of detailed single-neuron models (Kellems et al. 2010).

Functional Approach

Instead of reducing the system of differential equations, it can be more efficient to approximate

the solution. For a single external variable, y_1 , the general approach is summarized by the Volterra expansion:

$$\begin{aligned}x_1(t) &= \int F_1(t-s)y_1(s)ds \\ &+ \int \int F_2(t-s, t-s')y_1(s)y_1(s')dsds' \\ &+ \dots\end{aligned}\quad (3)$$

where F_1 and F_2 are functions that have to be determined empirically Bialek et al. (1991). Marmarelis and Naka (1973) used the Volterra expansion to model the membrane potential (x_1) given a time-dependent stimulus (y_1). In this approach, the state variable x_1 is seen as a functional of the external variable y_1 .

The Volterra expansion is an infinite series. Truncating the series leads to a reduction of model complexity. For neuron models, however, keeping only the two first terms is often insufficient. Indeed the nonlinearity of action potential generation requires higher-order terms.

Three other functional approaches can be seen as variants of the Volterra expansion: the cascade linear nonlinear model (LNL; Marmarelis and Marmarelis 1978; Korenberg and Hunter 1986), the nonlinear autoregressive Volterra model (NARV; Eikenberry and Marmarelis 2013), and the spike-response model (SRM; Kistler et al. 1997). In the cascade approach, the Volterra expansion is fed into a static nonlinearity. This nonlinearity can account for some of the nonlinear effects, thus reducing the relative importance of higher-order terms of the expansion. The NARV and SRM add a static nonlinearity as well but also a filter for the past spiking history. In the SRM, the subthreshold membrane potential is modeled as a sum of first-order effects from the external current y_1 and current pulses at the times of past action potential, y_2 :

$$\begin{aligned}x_1(t) &= \int K_1(t-s)y_1(s)ds \\ &+ \int K_2(t-s)y_2(s)ds\end{aligned}\quad (4)$$

where K_1 and K_2 are filter functions that must be determined empirically (see also reduction heuristics in Gerstner and Kistler (2002)). The likelihood of firing an action potential is a nonlinear function of x_1 . The NARV approach is distinct from the SRM in two points: the second external variable is a nonlinear function of the past $x_1(t)$, and second-order terms are included. All these variants were shown to improve the accuracy of the reduction.

Functional expansions rely on a proper method for estimating the filter functions. Calculating the Wiener filter is the classical method for finding a filter function such as F_1 , but multilinear regression can also be used. The Wiener filter and the multilinear regression are both based on a measurement of a correlation matrix between input (y_i) and output (x_1). Cascade models can be characterized using a correlation matrix (Hunter and Korenberg 1986; Chichilnisky 2001). Other variants such as the SRM are characterized using a gradient ascent of the likelihood to observe a given spike train (Paninski 2004) or using multilinear regression and likelihood ascent in two successive steps (Mensi et al. 2012).

Morphological Reductions

Dendritic and axonal processes have complex three-dimensional shapes. A detailed treatment of membrane potential and ion concentration on such a morphology is achieved by discretizing space.

When the membrane is passive and the system of equations is linear, drastic reductions are possible. For instance, Rall was the first to show the existence of an equivalent cable for dendritic trees. It is also Rall who described a Green's function approach consistent with the functional approach described above. His work is reviewed by Rall (1995).

A linear filter can still be applied for weakly active dendrites (Koch 1984) or nonuniform membrane conductances (London et al. 1999). For dendrites with strongly active ion channels or with elaborate distribution of synaptic conductances, these reductions do not apply.

Formal dimension-reduction methods apply well to dendritic trees. The use of singular

value decomposition was successfully applied to large dendritic trees (Kellems et al. 2009). The reduced models, however, remain fairly complex.

For a more drastic reduction, one approach has been to treat dendrites in terms of conceptually distinct compartments (Mel 2007). Each compartment can be modeled by more phenomenological models. One classical example is the Pinsky-Rinzel model which reduced pyramidal neuron models to a dendritic and a somatic compartment linked by a resistance (Pinsky and Rinzel 1994). Each compartment followed the dynamics of a restricted set of ion channels.

Reduction of Neural Networks

Neurons interconnect to form neural networks. Neuron model reduction can be applied to neural networks as well. Networks can be reduced to the dynamics of its subpopulations. The mean-field approach is often used for reducing a population of integrate-and-fire neurons (Renart et al. 2004). The mean-field approach can also be used to reduce a population of SRM neurons (Naud and Gerstner 2012). In both cases, the reduction of the network model is based on a simpler description of the single neurons. Neuron model reduction is more than an economy of equations and parameters; it creates a link between the different levels of description.

Definition

Neuronal parameter co-regulation is the exploration or alteration of distinct subsets of parameters (e.g., synaptic or membrane conductances) and how these parameters act in concert leading to changes in, or conservation of, neuronal output.

Detailed Description

The underlying ionic conductances found within a model neuron represent the parameters which determine the characteristics and output of a given model cell. These parameters are usually derived from biological data, such as voltage-clamp measurements of ionic conductance characteristics in defined cell types. The range over which these parameters can vary in a given system is referred to as the “parameter space” with a dimensionality dictated by the number of parameters allowed to vary in the system.

One area of interest in neuroscience, and a focus of modeling studies, is the interaction of distinct underlying physiological characteristics in the ultimate output generation of a neuron. In other words, the understanding of how relative contributions of conductances work in concert ultimately determines the voltage trajectory of a given neuron under different conditions. One computational method to probe for these relationships is the process of neuronal parameter co-regulation. In short, parameter co-regulation seeks to understand how conductances may work together as “modules” to constrain output, rather than each parameter being entirely independent (Franklin et al. 2010). Biological data have been accumulating for some time suggesting this to be a normal part of neuronal function, and are briefly discussed below. In addition, two computational methods to investigate this co-regulation are outlined below, utilizing both hand-tuning (Traub et al. 1991; De Schutter and Bower 1994) and model neuron database approaches (Prinz et al. 2003).

Biological: Correlation and Co-regulation of Ion Channels and Conductances

To some extent, the general concept of neuronal parameter co-regulation in neurons is rooted in part in studies that demonstrated the capacity of cells to homeostatically maintain appropriate output during perturbation of one or more different membrane conductances (Turrigiano et al. 1994; Desai et al. 1999; Golowasch et al. 1999; Galante et al. 2001; MacLean et al. 2003). These studies demonstrated that by experimentally manipulating specific membrane conductances and/or neuronal activity (pharmacologically, via gene expression, electrophysiologically), compensatory changes can occur among other conductances that stabilize and restore output of the cell.

These experiments not only laid the groundwork for an understanding of conductance co-regulation but also raised an important question: Is neuronal parameter co-regulation a fundamental aspect of cellular function or solely a

response to perturbation? This question makes the following prediction: if parameter co-regulation is a regular part of neuronal function, then populations of neurons should reveal existing relationships among conductances that are co-regulated. These relationships should include correlated patterns of ionic conductances, as well as perhaps other aspects of channel function (such as ion channel mRNAs), among the population of cells. Indeed, these relationships have been reported in multiple studies, including at the level of $G_{\max}/I_{\max}$ (Khorkova and Golowasch 2007; Ransdell et al. 2012; Temporal et al. 2012) as well as ion channel mRNA levels (Schulz et al. 2007; Tobin et al. 2009; Temporal et al. 2012). As an example, work by Ransdell et al. (2012) presented in Fig. 1 encapsulates these concepts from detecting correlated neuronal parameters (in this case I_A and I_{HTK}), demonstrating compensation to manipulating these conductances, and identifying compensatory upregulation of conductances that potentially underlies the compensation.

While many of these compensation and parameter co-regulation studies have focused on $G_{\max}$ or similar measures, this has more recently been extended to other conductance parameters. For example, in dopaminergic neurons of the substantia nigra, conductance values of I_A and I_H , which have been shown to be co-regulated in other systems (MacLean et al. 2003), were found to covary and interact at the level of their *voltage dependence* of their biophysical properties to influence rebound properties of these neurons (Amendola et al. 2012). Thus novel forms of neuronal parameter co-regulation continue to emerge through increasingly sophisticated experimental approaches.

Computational Approaches to Neuronal Parameter Co-regulation

Neuronal parameter co-regulation has been extensively studied using computational approaches, and modeling approaches have played a fundamental and formative role in our understanding of this phenomenon (LeMasson et al. 1993; Liu et al.

Neuronal Parameter Co-regulation, Fig. 1 Compensation and neuronal parameter co-regulation in a crustacean cardiac motor neuron. In cardiac “large cell” motor neurons of the crab, **(a)** I_A and I_{HTK} (high-threshold K^+) magnitudes are strongly negatively correlated across a population of cells among multiple individuals. **(b)** Representative recordings show an increase in I_A after block of I_{HTK} with tetraethylammonium (TEA) exposure (*left*) and an increase in I_{HTK} with block of I_A after 4-aminopyridine (4AP) exposure (*right*). Black

trace is the control, gray trace is the same cell after 60 min exposure to blocker. **(c)** Quantified effects of TEA (*left*) and 4AP (*right*) on the peak I_A and I_{HTK} , respectively. The same cell before (*black*) and after (*white*) is connected with a solid line. **(d)** Recordings of the effects of TEA exposure on network output over time show the ability of these cells to compensate (presumably through the increase in I_A shown in panel **c**) for block of the current to restore neuronal output. (Figure adapted from Ransdell et al. 2012)

1998; Prinz et al. 2003; Taylor et al. 2009). With the complexity of interactions among conductances within a neuron, and the experimental limitations in how many of these parameters effectively can be measured and manipulated, computational approaches have been at the forefront of these investigations. With more novel aspects of biophysical properties now being considered (Amendola et al. 2012), the complexity inherent in these systems continues to grow exponentially. Here we discuss a basic overview of two distinct ways in which computational approaches have been brought to bear on the concepts of parameter co-regulation.

Computational: Neuronal Parameter Co-regulation via Hand Tuning

A single model neuron can be chosen from within a given parameter space, with the final value for each of the parameters determined by the process of neuronal model hand tuning to match a specific neuronal output. The process of neuronal parameter co-regulation can then be applied to this model neuron to determine the impact on neuronal output when multiple parameters are altered in concert with one another. An example of such an approach is found in Soofi et al. (2012) as follows:

In this study, the authors are using a conductance-based model neuron to determine whether covarying pairs of parameters (membrane conductances) result in neuronal output that matches experimentally observed properties of spike phase maintenance in their biological neurons. Because their model neurons contain 8 distinct membrane conductances, there are 28 pairwise relationships between conductances that can be covaried. For illustrative purposes, we will look at one particular conductance pair, G_{CaT} vs. G_{Kd} . The investigators begin with a canonical value set for a model neuron with biologically relevant output. To study the effects of pairwise parameter variation on their output measure (spike phase), the G_{CaT} and G_{Kd} values were varied independently by multiplying the canonical value by a set of factors ranging from 0 to 3 in increments of 0.1. The investigators then quantified the impacts of this parameter co-regulation and determined that positive co-regulation of these two parameters leads to maintenance of neuronal output (as measured by spike phase), as seen in Fig. 2.

Neuronal Parameter Co-regulation, Fig. 2 Original voltage traces show that positively varying G_{CaT} and G_{Kd} supports spike phase maintenance. Three pairs of voltage traces are shown whose phase differences are highlighted on the bar plot. Traces are normalized by their respective periods; the first spike of each burst is aligned. The *lower* trace in each pair represents one burst from the canonical model neuron, marked on the plot with a *magenta square*. The *upper* trace represents one burst from a model for

Computational: Neuronal Parameter Co-regulation via Database Construction and Analysis

A population of model neurons that exists within a particular n -dimensional parameter space can also effectively be utilized to examine neuronal parameter co-regulation. For example, a neuronal parameter space exploration can be undertaken to first generate a population of model neurons. This population of model neurons can then either be selected for particular output features (Taylor et al. 2009; Ball et al. 2010) or subdivided into different output types (Prinz et al. 2003; Hudson and Prinz 2010) to determine whether relationships exist among subsets of parameters in the selected cells. An example of such an approach is found in Ball et al. (2010) as follows:

In this study, the authors are using a conductance-based model neuron database to determine whether covarying sets of parameters (membrane conductances) result in neuronal output that matches experimentally observed

which G_{Kd} and G_{CaT} varied from their canonical values. *Black lines* drawn between action potential peaks in the *upper* and *lower* traces show the divergence in phase between every third action potential of each burst. Traces in the *insets* have not been normalized by period to demonstrate the differences in the periods between the original and canonical bursts. (Data reproduced with permission from Soofi et al. 2012)

Neuronal Parameter Co-regulation, Fig. 3 Maximal conductance relationships in a population of randomly generated neuron models constrained by χ^2 values representing the model output. A, Distribution of model cells in two representative three-dimensional plots: G_{KCa} , G_{CaT} , and G_{Kd} (top) and G_{CaT} , G_{CaS} , and G_A (bottom). The axes represent conductance values as multiples of those in the nominal model. (Data reproduced with permission from Ball et al. (2010))

properties of driver potential generation in their biological neurons. Their model neurons contain 7 distinct membrane conductances, which vary over a continuous 0.1x–5x range from the canonical model parameter values. To determine whether any parameter co-regulation was responsible for the observed output, the investigators randomly simulated thousands of different 7-dimensional conductances sets and then selected only those neurons that had biologically relevant output. This method of “rejection sampling” (Robert and Casella 2004) results in a population of model neurons with appropriate output, but no predetermined conductance values. After selecting based on distinct output features,

the investigators determined that multiple parameter co-regulation patterns emerged among the ionic conductances in their data, including two 3-way relationships as seen in Fig. 3.

Neuronal Parameter Non-uniqueness

Jean-Marc Goaillard
Inserm, UMR_S 1072, Marseille, France
Aix-Marseille Université, UNIS, Marseille, France

Synonyms

Degeneracy; Distributed robustness; Neutral space

Definition

Parameter non-uniqueness refers to the ability of biological systems to generate a similar (or even identical) functional output using vastly different solutions in the properties of their underlying components. As such, parameter non-uniqueness is tightly linked to the notion of degeneracy but also to the notion of neutral space, which refers to regions of a parameter space where variations in the parameters' values have no effect (therefore, the term neutral) on the system's output (function/phenotype) (Wagner 2005).

Methodologically, however, parameter non-uniqueness means that the dynamics of a biological system such as the neuron might not be captured by modeling a unique set of parameters but rather by modeling a population of models covering the biological neutral space of solutions (non-unique sets of parameters) (Marder and Taylor 2011).

Detailed Description

Background: Non-uniqueness of Parameters in Non-neuronal Systems

The fact that biological systems are able to generate identical phenotypes using variable solutions has been experimentally observed in various biological systems at multiple integration levels. The most famous example is probably the degeneracy of the genetic code, whereby the same amino acid is encoded by up to six different nucleotide triplets (Goldberg and Wittes 1966). But the first observation of parameter non-uniqueness has probably to be attributed to the English embryologist Conrad Hal Waddington who suggested that the development of biological organisms is surprisingly stable in the face of the numerous, and often deleterious, genetic variations observed across individuals (Waddington 1957). Recent studies on the development of the nematode *Caenorhabditis elegans* have directly demonstrated that various genetic and cellular solutions are available to generate a stable vulval organ (Félix and Wagner 2006), such that genetic mutations or loss of one cell type does not prevent

correct organ development. These examples illustrate how parameter non-uniqueness relates to the notion of distributed robustness, where the robustness of a biological system is distributed among many distinct components, such that failure (or strong variation) in one of the components does not compromise function or phenotype (Wagner 2005).

Multiple Biophysical Solutions for a Same Pattern of Neuronal Activity

Similar examples have been observed at the neuronal level, in particular concerning the multiple biophysical solutions (combinations of ion channels) used by neurons to generate a same pattern of firing (Marder and Goaillard 2006). While pharmacology experiments using toxins targeting ion channels have long demonstrated that partial blockade of most voltage-dependent ion channels

strongly alters neuronal output, a number of experimental studies have demonstrated that the level of expression of a specific ion channel can vary in a twofold to fivefold range across neurons of the same type, even when these neurons display virtually identical patterns of activity (Marder and Goaillard 2006; Fig. 1a). Therefore, the combinations of levels of expression of the voltage-dependent ion channels used by one given neuronal type to generate its archetypal pattern of activity are non-unique. The non-uniqueness of neuronal parameters is probably best demonstrated by the extreme case of transgenic animals where genes coding for specific ion channels have been deleted: several studies have indeed demonstrated that neurons of a given type may continue to produce their typical pattern of activity even in the absence of one of their essential ion channels (such as a fast sodium channel, or a transient potassium channel). One may believe that this compensation is due to the presence of

Neuronal Parameter Non-uniqueness, Fig. 1 Non-uniqueness of biophysical parameters in biological and theoretical crustacean neurons. (a) top, voltage traces from two lateral pyloric (LP) neurons recorded from two different animals and displaying highly similar firing patterns. Bottom, bar plots showing the conductance levels (left) and the expression levels (right) of three potassium channels (*shab*, *g_{Kd}*; *BK-KCa*, *g_{KCa}*; *shal*, *g_A*) involved in the electrophysiological activity of the LP neuron. Although the two LP neurons display virtually identical patterns of activity, their underlying conductance levels or the expression levels of the corresponding ion channels are quite different. (b) top, voltage traces of two multi-compartment Hodgkin-Huxley LP models generated by

randomized screening of the parameter space and displaying highly similar firing patterns. Bottom, bar plot showing the conductance levels and gating properties of the conductances most significantly involved in defining the firing pattern of the LP neuron. As with the biological LP neurons, the two models display highly variable underlying biophysical parameters (bottom) that contrast with their similarity in activity patterns (top). Color coding: red on top corresponds to a higher value for the red LP neuron, blue on top corresponds to a higher value for the blue LP neuron. Scale bars in (a) and (b) correspond to the same time and voltage ranges (a: Modified from Marder and Goaillard 2006. b: Modified from Marder and Taylor 2011)

fully functionally redundant ion channels, whose function is revealed by the absence of the deleted ion channel; but the loss of a transient potassium channel in pyramidal neurons is in fact compensated by a compensatory increase in expression of a delayed rectifier potassium channel already expressed by the neuron in normal conditions. There again, the presence of non-unique combinations of parameters (including solutions where one parameter takes the 0 value) provides the neurons with robustness to perturbations, in particular genetic losses of function. Moreover, recent studies have demonstrated that the non-uniqueness of ion channel parameters not only applies to levels of expression but also to the gating properties of ion channels (voltage-dependence, kinetics): similar patterns of activity are generated by neurons presenting highly variable voltage dependences (up to 20 mV variation across neurons of a same type) for a same ion channel.

In the face of these experimental observations, several theoretical studies have been performed using dense screening of parameter spaces (database approaches) instead of hand-tuning of parameters. Maximal conductance values for each ion current were varied over a large range to simulate the observed variations in expression levels, and variability in the gating properties was also included (for review, see Marder and Taylor 2011). Consistent with the experimental results discussed before, these studies have demonstrated that myriad solutions are available to generate a given type of activity, even when complex models of neurons or of small neuronal networks (multi-compartment Hodgkin-Huxley modeling with up to 16 different biophysical parameters) are considered (Fig. 1b). These studies suggested that non-unique solutions are available because of the dense functional overlap between ion channels and the pleiotropy of ion channels: each firing feature (action potential threshold, resting membrane potential, firing frequency, etc.) is defined by the activity of several functionally overlapping ion channels while each ion channel usually participates in defining several distinct firing features (pleiotropy). The necessity to have functionally overlapping pleiotropic components to generate non-unique

solutions is not specific to the non-uniqueness of neuronal parameters, but rather seems to be a general feature of robust biological systems. Conrad Hal Waddington was the first one to identify these two properties as underlying the robustness of development of biological organisms to genetic variations (Waddington 1957).

Random or Nonrandom Solutions?

The essential question that arises from these experimental and theoretical observations is whether the non-unique solutions are mainly random, meaning that parameters can be varied independently (and the neutral space has pretty much a Mexican hat shape corresponding to random Gaussian variation of each parameter), or whether the neutral space of non-unique solutions has a specific shape suggesting that equivalent solutions correspond to correlated variations in parameters. Here appear the first discrepancies between experimental studies and theoretical studies: while theoretical studies suggest that no correlation in underlying parameters is needed to model a same firing pattern, experimental studies have demonstrated the widespread occurrence of correlations in the levels of expression of ion channels (discussed in the ► [“Neuronal Parameter Co-regulation”](#) entry) (Marder and Goaillard 2006). While it is tempting to speculate that correlations in functionally overlapping ion channels may “help” find equivalent solutions for a same pattern of activity, the discrepancies between theory and biology mainly suggest that correlated variations in neuronal parameters are not needed per se to perform a same computational operation, but that they may rather represent responses to non-computational biological constraints (such as limiting the energy expenditure of the neuron) that are not taken into account in theoretical models of neuronal activity.

Neuronal Parameter Sensitivity

A. V. Olifer
School of Science and Technology, Georgia
Gwinnett College, Lawrenceville, GA, USA

Definition

Sensitivity of a quantity to a parameter at a fixed point of the parameter space measures the relative change of the quantity in relation to a relative change of the parameter. There are two interrelated formal definitions of sensitivity.

Consider a real-valued function $C = C(p)$ of a real variable p . Let $C(p)$ be defined for the two values of p , $p = p_0$ and $p = p_0 + \Delta p$, where Δp is some number. Then sensitivity S of $C = C(p)$ to the change of p from p_0 to $p_0 + \Delta p$ is defined as

$$S = \frac{C(p_0 + \Delta p) - C(p_0)}{C(p_0)} \div \frac{\Delta p}{p_0}. \quad (1)$$

For example, $S = 2$ means that the relative increase of $C(p)$ from $C(p_0)$ to $C(p_0 + \Delta p)$ is two times the relative increase of p from p_0 to $p_0 + \Delta p$. Notice that in Eq. 1, the value of S depends on p_0 and Δp and there are no other

requirements to $C(p)$ except for it being defined for $p = p_0$ and $p = p_0 + \Delta p$.

If the function $C = C(p)$ is differentiable at p_0 , then S is defined as

$$S = C'(p_0) \frac{p_0}{C(p_0)}, \quad (2)$$

where $C'(p_0)$ is the derivative of C at $p = p_0$. In this case, S does not depend on Δp .

Formula (2) requires an explicit formula for $C'(p_0)$. In neuronal modeling, such formulas are rarely known. Using Eq. 1 instead of Eq. 2 is equivalent to using the approximation

$$C'(p_0) \approx \frac{C(p_0 + \Delta p) - C(p_0)}{\Delta p} \quad (3)$$

instead of the exact value of $C'(p_0)$ in Eq. 2.

Detailed Description

Informally, the sensitivity of an entity to a parameter quantifies how much the entity changes given a small change of the parameter. In neuronal modeling, such entities can be the period of tonic spiking, the maximal value of the membrane potential during a spike, the total value of calcium entering the neuron during a spike, etc. Accordingly, a parameter could be any factor that specifies the neuronal (synaptic or network) model, such as, for example, the maximal conductance of an ionic current, the size of a dendrite, the duration of an applied current, and so on.

In what follows, we clarify some important subtleties of calculating and using sensitivities, and then as an example, consider an application of sensitivity analysis to an important physiological problem.

Theory

An obvious requirement for using Eqs. 1 and 2 is $C(p_0) \neq 0$ since relative changes to zero values are not defined. Hereafter, we assume that this requirement holds.

Another basic requirement for Eq. 1 is that $C(p_0 + \Delta p)$ exists. This may not be the case if at some value of p between p_0 and $p_0 + \Delta p$ the dynamical system under consideration experiences a bifurcation. For example, if C is the period of neuronal bursting, then at $p_0 + \Delta p$, the system may have no periodic solution at all (Izhikevich 2010). In some cases, sensitivities can be evaluated near the points of bifurcation using special methods of bifurcation theory. We do not consider such methods here. In this entry, we assume that the parameters of the model are not close to bifurcation values. In what follows, we also assume that there is no explicit formula for $C'(p_0)$. If such formula is known, then calculation of S according to Eq. 2 is trivial.

A sensitivity calculated using Eq. 1 for just one new value of the parameter is of limited value. For example, one may explore how an entity changes when one of its parameters changes by 1% and determine a parameter to which the entity is most (or least) sensitive. However, such a result will be specific for 1% changes of the parameters. For 0.5% parameter changes, the entity may be most (or least) sensitive to other parameters.

Because of these considerations, sensitivities are most worthwhile when they essentially do not depend on the magnitudes of relative parameter changes when the latter are sufficiently small. Exact independence is possible only in the case when $C = C(p)$ depends on p linearly. Then the approximation (Eq. 3) gives the exact value of $C'(p_0)$ for any Δp . In all other cases, the calculated value of sensitivity S is an approximation to the limit value of S for $\Delta p \rightarrow 0$ provided the limit value exists.

When C has the first and the second derivatives at $p = p_0$, the existence of the limit follows from the following expression for the error of the approximation (Eq. 3):

$$C'(p_0) - \frac{C(p_0 + \Delta p) - C(p_0)}{\Delta p} = \frac{\Delta p}{2} C''(\xi). \quad (4)$$

Here, ξ is some value of p from the interval $(p_0, p_0 + \Delta p)$. The theory does not specify the value of ξ ; it claims only that such a value exists

(Thomas et al. 2009). The expression in the right-hand side of Eq. 4 has the limit of zero when $\Delta p \rightarrow 0$. Because of that, the limit

$$\lim_{\Delta p \rightarrow 0} \frac{C(p_0 + \Delta p) - C(p_0)}{\Delta p}$$

exists and is equal to $C'(p_0)$.

A limit may also exist when $C(p)$ is defined only at discrete values of p . In this case, it is a limit of a sequence.

In some cases, continuity and differentiability of C are known or can be proved. A notable example is the period of a periodic solution to a neuronal model of the form

$$\frac{dx}{dt} = F(x; p). \quad (5)$$

Here, x is the vector of dependent variables (membrane potentials in compartments, activation variables, etc.). Vector function $F = F(x; p)$ depends on x and parameter(s) p . Suppose F is differentiable with respect to the components of x and p and suppose when $p = p_0$, the system (5) has a periodic solution with the period $T = T(p_0)$. Then for p near p_0 , the system also has a periodic solution with a period $T(p)$, and $T(p)$ is differentiable at p_0 (see, e.g., Hartman 1964). This result provides a basis for exploring sensitivity of $T(p)$ to various parameters (see, e.g., Olypher and Calabrese 2007).

In general, differentiability of F with respect to the components of x and p implies differentiability of the solution $x = x(t, p)$ with respect to p . In some cases, this fundamental property can be used to prove differentiability of $C(p)$.

Generalizations

Most often, $C = C(p)$ depends on a number of parameters so that p is a vector: $p = (p^1, p^2, \dots, p^n)$. If there exists a partial derivative $\frac{\partial C(p_0)}{\partial p^i}$ of C with respect to p^i at $p_0 = (p_0^1, p_0^2, \dots, p_0^n)$, then the sensitivity of C to p^i at $p = p_0$ is defined (cf. Eq. 2) as

$$S = \frac{\partial C(p_0)}{\partial p^i} \frac{p_0^i}{C(p_0)}. \quad (6)$$

Formula (6) can be generalized to define sensitivities with respect to simultaneous changes in several parameters.

For example, let S_i be the sensitivity of C to p^i and S_j be the sensitivity of C to p^j , $i < j$, at $p = p_0$ defined according to Eq. 6. Then, a weighted sum of S_i and S_j approximates the relative change of C when p changes from p_0 to $\hat{p} = (p_0^1, \dots, p_0^i + \Delta p^i, p_0^{i+1}, \dots, p_0^{j-1}, p_0^j + \Delta p^j, \dots, p_0^n)$:

$$\frac{C(\hat{p}) - C(p_0)}{C(p_0)} \approx S_i \cdot \frac{\Delta p^i}{p_0^i} + S_j \cdot \frac{\Delta p^j}{p_0^j}$$

Since

$$C(\hat{p}) - C(p_0) \approx \frac{\partial C(p_0)}{\partial p^i} \Delta p^i + \frac{\partial C(p_0)}{\partial p^j} \Delta p^j. \quad (7)$$

Notice that if Δp^i and Δp^j are chosen such that

$$\frac{\partial C(p_0)}{\partial p^i} \Delta p^i + \frac{\partial C(p_0)}{\partial p^j} \Delta p^j = 0 \quad (8)$$

then according to Eq. 7, $C(p)$ does not change in a linear approximation.

Calculating Sensitivities

Most commonly, validity of sensitivity values is established empirically. In the simplest case, one calculates S for a sequence of decreasing values of Δp and notices convergence of the calculated values of S to some value. Then the final result is chosen depending on the accepted level of accuracy. For example, it can have two decimal places.

If convergence is not apparent, then one possibility is that C depends highly nonlinearly on p near $p = p_0$. Such a situation is not rare since dynamical systems often model neuronal behavior best of all when the system parameters are close to their bifurcational values (Izhikevich 2010). If this is the case, then the sensitivity analysis is not applicable.

Sometimes S does converge to some value with the decrease of Δp , but the convergence is slow. That can be caused by the limited accuracy of the calculated values of $C(p_0 + \Delta p)$. For example, the system may need a considerable simulation time to get to an attractor state, it may be an accumulation of round-off errors, etc. Then it may be possible to improve the convergence of $S = S(\Delta p)$ using various techniques that can be found in textbooks on numerical methods in sections on numerical differentiation (see, e.g., Atkinson 1989).

For example, one can use more accurate approximation formulas for the first derivative such as

$$C'(p_0) \approx \frac{C(p_0 + \Delta p) - C(p_0 - \Delta p)}{2\Delta p}.$$

A related technique is using Richardson extrapolation where the approximations to $C'(p_0)$ obtained for different values of Δp are combined in a special way to increase the accuracy of the result (Atkinson 1989).

Application

The popularity of the sensitivity analysis in neuroscience rests on three factors. First, the concept of sensitivity is appealing to experimentalists who study how neuronal responses change provided certain changes of experimental parameters. Second, the formula (1) for calculating sensitivity is very simple. Finally, the values of sensitivity obtained often make sense and help to understand neuronal functioning.

Sensitivities make changes of various entities comparable. For example, if one entity changes by 10% and another by 5% when a parameter changes by 1%, then we conclude that the first entity is two times more sensitive to the changes of the parameter than the other one even if the units of those entities are different, e.g., millivolts and milliseconds. In models, such comparability is often achieved by making all dependent and independent variables and all parameters in the model dimensionless and normalized. For example, a normalization of the membrane potential $V(t)$ can be

achieved by substituting $V(t)$ with another variable, $V(t)/V_{max}$, where V_{max} is a maximal value of $V(t)$ during a spike. Partial derivatives calculated for dimensionless and normalized variables are conceptually similar to sensitivities.

Sensitivity analysis has proven to be a valuable tool in various studies of neuronal modeling. One particular application relates to the exploration of activity-dependent homeostatic regulation in neurons. Experiments show that neurons can maintain their functionality by readjusting biophysical properties, such as densities of ionic channels, in response to external changes (see, e.g., Khorkova and Golowasch 2007). An important general question is how changes in some model parameters can be compensated for by changes in other parameters, so that the system's output is preserved.

In neuronal models, possible compensatory changes of parameters can be revealed by computing sensitivities or more precisely the corresponding partial derivatives. In the example below, this was done for a model of a central pattern generator that paces the heartbeat in the leech (Lamb and Calabrese 2012). The model consists of two neurons that inhibit each other; g_{SynS} is the maximal conductance of the synaptic current. Each neuron is an intrinsic rhythmic burster for the parameter values considered. One of the ionic currents that makes rhythmic bursting possible is a hyperpolarization-activated inward current with the maximal conductance g_h . The model shows a good match with experimental output when $g_{SynS}^* = 150nS$ and $g_h^* = 4nS$. For this set of parameters, p^* , the model demonstrates stable alternating bursting of the neurons with the period $T(p^*) = 7.91$ s. Suppose g_{SynS} increases or decreases. What change of g_h can compensate for the change g_{SynS} to preserve the period $T = 7.91$ s?

Let in Eq. 8 $C = T$, $p^i = g_{SynS}$, and $p^j = g_h$. Then according to Eq. 8, the equation for the compensatory change of g_h in linear approximation has the form

$$g_h = \chi \cdot (g_{SynS} - g_{SynS}^*) + g_h^* \quad (9)$$

where $\chi = -[\partial T(p^*)/\partial g_h]^{-1} \cdot [\partial T(p^*)/\partial g_{SynS}]$. Calculations have shown that $\chi = 0.012$.

Equation 9 describes a line in the plane of g_{SynS} and g_h that has a slope of 0.012 and passes through the point (150, 4). Linearity of the approximation means that when g_{SynS} and g_h change along the line (Eq. 9), the deviation of the period from the value of 7.91 s is close to a linear combination of the quadratic terms $(g_{SynS} - 150)^2$, $(g_h - 4)^2$, and $(g_{SynS} - 150) \cdot (g_h - 4)$. The closer the point (g_{SynS}, g_h) is to the point (150, 4), the closer is the corresponding period to 7, 91.

Exact compensation is achieved when g_{SynS} and g_h change along a curve to which the line (Eq. 9) is the tangent line at point (150, 4). The existence of such a curve follows from the implicit function theorem (Conway 1990; Thomas et al. 2009). One of the key premises of the theorem is that $\partial T(p^*)/\partial g_h \neq 0$. In the case considered, the estimated value of $\partial T(p^*)/\partial g_h$ was -0.63 s/nS.

The above analysis can be generalized to the case of more than two parameters. Suppose there are m independent characteristics of a neuronal model, defined at a point p^* of an n -dimensional parameter space. The implicit function theorem states that under certain conditions, there is a manifold passing through p^* such that m characteristics do not change their values when the parameters vary along the manifold. In the above example with g_{SynS} and g_h , the curve was a manifold of dimension one. In the general case, the dimension of the manifold is equal to $n - m$. The theory shows that even if one parameter in the model changes, then to compensate for its change and preserve the values of all m characteristics, one has to change at least m other parameters.

Partial derivatives of the characteristics with respect to the parameters at p^* are the coefficients of the hyperplane tangent to the manifold at the point; in the example above, the tangent hyperplane was a tangent line. Changes of the parameters along the hyperplane do not change the values of the characteristics in linear approximation.

If the dimension of the parameter space is equal to n and only one characteristic C is considered, then the manifold passing through p^* has dimension $n-1$. The gradient of C at p^* , $\nabla C(p^*) = (\partial C(p^*)/\partial p^1, \partial C(p^*)/\partial p^2, \dots, \partial C(p^*)/\partial p^n)$, is orthogonal to the manifold at p^* and shows the direction and magnitude of the greatest rate of increase of C at p^* .

Sensitivity of neuronal models to parameters can be studied by other methods. In particular, one may create a database of characteristics of neuronal models obtained for various values of the model parameters and then use data mining methods to identify how parameter changes affect the characteristics (Hudson and Prinz 2010). The accuracy of such analysis depends considerably on the grid of the parameter points for which the model is simulated. An advantage of this approach is that it provides information for large domains of the parameter space.

In summary, the sensitivity analysis is a relatively simple computational tool that helps understand smooth changes in neuronal and network properties resulting from small changes of the model parameters near a point of the parameter space. This tool is effective when the neural characteristics of interest exist for all the parameter values considered and do not change abruptly. In all the circumstances, numerical accuracy is a critical condition for an application of the sensitivity analysis.

Neuronal Parameter Space Exploration

Wafa Soofi

Biomedical Engineering Department, Georgia Institute of Technology/Emory University, Atlanta, GA, USA

Synonyms

Neuronal parameter space search; Sweeping the parameter space of neuron models

Definition

A parameter is a measurable characteristic that is used to define a system. The range of possible values that a parameter can assume is referred to as *parameter space*. The number of dimensions of the parameter space is equal to the number of parameters that is allowed to vary. *Exploration* of the parameter space is the act of choosing various sets of parameter values within the space and determining the resultant output of the system. *Neuronal parameter space exploration* is the investigation of the parameter space for a model of a single neuron or neuronal network.

Detailed Description

Neuron Model Hand-Tuning and Optimization Techniques

A common interest among neuroscientists is to determine the underlying parameters of a particular biological neuron from experimental data, such as a recorded voltage trace. A neuroscientist might approach this problem by using a *neuron model*, for which the output and underlying parameter values are known (Dayan and Abbott 2001). One way of using a neuron model to estimate the parameters of a biological neuron is to (1) vary the parameters of the neuron model, (2) determine the model output, and (3) make further modifications to the parameter

values based upon the difference between the model output and the output of the biological neuron. The above steps are repeated until the model output matches the biological output within an acceptable margin of error. The terminal set of parameter values for the neuron model is then a candidate for the unknown parameters of the biological neuron (Marder and Selverston 1992). This method of parameter space exploration, if performed in such a way that the user monitors the output of the search process and continually makes adjustments to the parameters, is known as hand-tuning (Mainen and Sejnowski 1998; Prinz et al. 2003; Haufler et al. 2007; see entry on ► [“Neuronal Model Hand-Tuning”](#)). Such a process can also be automated, either by applying heuristic methods for neuronal model generation or by the use of brute-force construction and exploration, as described below.

Due to the complexity of modern neuron models, the act of hand-tuning model parameters can be slow and difficult. Automated optimization techniques are commonly used instead (Van Geit et al. 2008). There are two major components of these optimization techniques that are generally independent of one another. The first component is the error function which indicates how closely the model output, given the chosen parameters, matches the target output. The fitness function (see entry on ► [“Neuronal Model Output Fitness Function”](#)) serves a similar purpose to the error function. In general, when matching model output to some target output, one desires to minimize the error function or maximize the fitness function.

Error functions may be constructed in many ways. For example, one might use a feature-based approach by comparing single features of interest in the biological data (e.g., spike height or firing rate) to those same features in the model data. Another method is to perform a point-to-point comparison between the model and biological data by calculating the root-mean-square of the difference between their voltage traces (Van Geit et al. 2008). One can also calculate several feature-based error functions and determine a set of trade-off solutions that takes all of them into account (Druckmann et al. 2007; Handl et al.

2007; Smolinski and Prinz 2009; see entry on ► [“Multi-objective Evolutionary Algorithms”](#)). Several other types of error functions exist; the best choice is largely dependent upon the features of the data that are germane to the research question at hand.

The second component of automated optimization techniques is the search algorithm, which is the method used to minimize the error function. There are many types of search algorithms. Examples include evolutionary algorithms (see entries ► [“Evolutionary Algorithms”](#) and ► [“Multi-objective Evolutionary Algorithms”](#)), genetic algorithms, and gradient descent algorithms. In theory, for an optimization problem, it is often desired that a search algorithm will terminate at the global minimum (i.e., where the value of the error function is smallest). In the case of neuron models, finding a single global minimum is often not possible. It is more feasible to instead seek a set of solutions that resembles the target activity to a degree that is deemed acceptable by the user (Van Geit et al. 2008).

Neuron Model Database Construction and Analysis

N

Another interest of neuroscientists is to gain a holistic understanding of how *all* model parameters affect model output. One might be interested, for example, in knowing how neuronal output is affected when two or more parameters are varied at once (see entry on ► [“Neuronal Parameter Co-regulation”](#)). In this case, one first simulates the neuron model output for every possible combination of parameter values within chosen ranges and then analyzes the information afterward. This alternative method of parameter space exploration is referred to as the construction and analysis of neuronal model databases (Prinz et al. 2003, 2004; Marder and Goaillard 2006; see entry on ► [“Neuronal Model Databases”](#)).

A neuroscientist may be interested in gaining an overall understanding of how the underlying parameters of neuron models influence neuronal output, rather than finding a parameter set that produces model output matching a specific set of

experimental data. In this case, constructing a neuron model database (or analyzing a previously constructed one) may be a more appropriate method of neuronal parameter space exploration than an automated optimization technique. To construct a neuron model database, one can choose an appropriate range for each parameter in the neuron model and then cover the entire parameter space with a randomly or evenly distributed set of simulation points (see entry on ► [“Neuronal Model Databases”](#)). One can then define a solution space of interest by (1) choosing a range of values for any given feature(s) of neuronal output (e.g., a burst duration of 0.5–0.6 s) and then (2) stipulating that any neuron models exhibiting output feature values that fall within the designated range are part of the solution space. The database, which contains both the output measure values and parameter values for each model, provides information on where the solution space is located in parameter space. This approach, known as ensemble modeling, takes into account the variability of both input parameters and output features in neuron models (Prinz 2010). By examining the location and shape of the solution space, the researcher can determine the sensitivity of the neuronal output to each parameter (see entry on ► [“Neuronal Parameter Sensitivity”](#)), as well as the effect of varying two or more parameters at once on the neuronal output (see entry on ► [“Neuronal Parameter Co-regulation”](#)). One can also gain insight into whether very different parameter sets can result in similar output and, conversely, whether very similar parameter sets can produce dissimilar outputs (see entry on ► [“Neuronal Parameter Non-uniqueness”](#)).

Choosing a Method of Neuronal Parameter Space Exploration

In the case of hand-tuning neuron models, one uses the output from the previous parameter set to inform which parameter set to examine next. An analogy can be drawn to making an expedition to an unexplored jungle and using clues from the environment to locate a specific object, such

as a downed aircraft. In the case of database construction, the model output does not inform the direction of exploration (i.e., which parameter values are chosen for modification); rather, the entire space is first explored and then analyzed *post hoc*. Within our jungle analogy, this type of analysis is akin to an expedition that maps the entire jungle. Greater resources are required to complete the latter task, but a more complete view of the system’s output emerges from the analysis.

Neuronal parameter space exploration can take on many forms. Which method is “best” is strongly dependent upon the researcher’s scientific question.

Neuronal Parameter Space Search

► Neuronal Parameter Space Exploration

Neuronal Parameter Space Visualization

Michael Schmuker
Sussex Neuroscience, CCNR, Informatics,
University of Sussex, Brighton, UK

Definition

The visual display of the behavior of a neuron, a neuron model, or a network of neurons or neuron models, for a number of parameters which govern model behavior or describe a series of observations.

Detailed Description

Computational neuron and network models have a number of free parameters that influence the models' behavior. For example, a leaky integrate-and-fire model may allow for adjusting two parameters, the leak conductance and the resting potential. More parameters are needed to characterize more elaborate point neuron models like the Izhikevich model (4 parameters; Izhikevich 2007) or the exponential adaptive integrate-and-fire model (6 parameters, Gerstner and Brette 2005). Biophysical models that contain cable equations for passive membranes and Hodgkin–Huxley-type dynamics for active channels easily reach parameter counts of a dozen or more. Even higher parameter counts are achieved when coupling several neurons in a network, since synaptic coupling strengths have to be taken into account (Prinz et al. 2003).

A straightforward approach is to visualize parameters in a pair-wise fashion on the two-dimensional plane. In this approach, the output of the model is encoded into a single variable, the *fitness function*. As an example, Fig. 1a shows a simple network that consists of three neuronal populations and two Poisson spike sources which drive a population of integrate-and-fire neurons. It is uncomplicated to visualize the effect that the firing rates of the excitatory and the inhibitory populations have on the firing rate of the target population (Fig. 1b): The firing rate of the inhibitory population r_{inh} is plotted on the x-axis and the firing rate of the excitatory population r_{exc} is plotted on the y-axis. The firing rate of the target population is encoded in the color of the “pixel” at the associated coordinates. Therefore, this approach is also termed “pixelization.” The same strategy can be applied to visualize the effect of changing the synaptic weights of both populations on the target population, w_{inh} and w_{exc} (Fig. 1c). These plots represent a two-dimensional slice through the parameter space of the network model. The resulting visualization is easy to interpret.

For complex models, more than two parameters need to be accommodated in the visualization. This can be achieved by dimensional

Neuronal Parameter Space Visualization, Fig. 1 (a) A sample network to explore multidimensional parameter visualization. The excitatory and inhibitory populations are modeled as Poisson populations consisting of 200 and 50 independent Poisson processes, respectively. They project on the neurons in the target population with connection probability $p_{conn} = 0.1$. The target population consists of 30 integrate-and-fire neurons. Network code is available online (Schmuker 2013). (b) Average spike count of neurons in the target population for $w_{exc} = w_{inh} = 10$ fS and

varying input firing rates. (c) Average target neuron spike count for $r_{exc} = r_{inh} = 30$ spikes/s and varying input weights. (d) Visualization of the effect of all four parameters r_{exc} , r_{inh} , w_{exc} , and w_{inh} on target spike count by dimensional stacking. For example, in the lower left 5×5 tile, the weights are constant at $w_{\{inh,exc\}} = 8$ fS, while r_{inh} and r_{exc} vary. In the next 5×5 tile to the right, identical parameters are used except that w_{inh} has increased by one step. In the upward direction, w_{exc} is increased

stacking (LeBlanc et al. 1990; Taylor et al. 2006), which allows visualizing a much larger number of parameters on the two-dimensional plane. First, the network performance is evaluated for each parameter combination on a discrete grid. Each evaluation yields a one-dimensional “fitness” value which can be encoded into a color code. Dimensional stacking projects the multidimensional parameter grid onto the two-dimensional plane in a hierarchical fashion without any loss of information (Fig. 1d). Considering the network in Fig. 1a, it is possible to visualize the effect of all four parameters r_{inh} , r_{exc} , w_{inh} , and w_{exc} in a single plot using this approach.

Dimensional stacking is well suited to visualize the parameter space of complex models with many

parameters (see Taylor et al. 2006 for examples). However, it requires that parameter combinations are sampled on a regular, discrete grid. The resolution of the grid is limited by practical constraints of computing power: For example, if p parameters are each to be sampled at s sample points, the number of simulations needed is s^p . Hence, achieving a good resolution in parameter space becomes very difficult with increasing parameter numbers. Also, the arrangement of parameters in the visualization hierarchy has great influence on the interpretability of the display (i.e., which parameter varies most quickly on each axis, which one second most quickly, etc.). Certain heuristics can be used to come up with a useful arrangement (see Taylor et al. 2006 for an overview).

In cases where regular sampling is not possible or not practical, other approaches can be used to visualize neuronal parameter space. For example, observed model states can be plotted on a two-dimensional plane. Consider the shape of an action potential, which can be characterized by its height in mV and width at half-maximum. For an ensemble of action potentials produced by a family of neuron models, the distribution of spikes can be plotted as points in this two-dimensional parameter space (see Fig. 2f in Prinz et al. 2003). Dimensionality reduction techniques can be applied if more parameters need to be visualized, like principal component analysis (PCA) or multidimensional scaling (MDS). For more complicated parameter landscapes, nonlinear approaches to low-dimensional embedding have been put forward, like ISOMAP (Tenenbaum et al. 2000) and locally linear embedding (LLE, Roweis and Saul 2000). These methods are able to accurately represent manifolds embedded in high-dimensional space. Such manifolds may occur, for example, if some of the parameters are interdependent or if the model design forbids certain parameter combinations.

Definition

The *neuronal population vector* is the outcome of a computation by which weighted neural activities of individual elements in a population yield an estimate of the population's functional operation.

Detailed Description

The neuronal population vector is the outcome of a computation. It requires a behavioral measure in multidimensional space, a neuronal population, and an orderly variation of neural activity of the constituent elements in the population with the behavioral measure. The computation is a *weighted vectorial sum* of neural activities that

yields an estimate of the behavioral measure. In the original application (Georgopoulos et al. 1983), the behavioral measure was the direction of arm movement in 2-D space, the neuronal population consisted of cells recorded extracellularly in the monkey motor cortex during movements of different directions, and the orderly variation of neural activity was the *directional tuning* of rate of firing of action potentials, manifested as highest activity with movements in a particular direction (the cell's *preferred direction*) and progressively less activity with movements farther and farther away from the preferred direction. The plot of cell activity against movement direction yields a directional *tuning curve*. An example of directional tuning and preferred direction is shown in Fig. 1.

More generally, neural activity can come from single cells, multiunit activity, signals derived from integrated synaptic events (e.g., electroencephalogram, magnetoencephalogram), or other signals indirectly related to neural events (e.g., functional magnetic resonance imaging).

In the following example, we have (a) the direction of movement, $\vec{M}$; (b) the neuronal population consisting of N cells; (c) the preferred direction of the i th cell, $\vec{C}_i$, a vector of unit length; (d) the cell activity (or its change from a given level) for movement $\vec{M}$, $d_{i\vec{M}}$; and (e) a weight $w_{i\vec{M}}$ defined as a scalar multiplier $F(d_{i\vec{M}})$. Then, the population vector $\vec{P}(\vec{M})$ is the direction of movement estimated from the neural activity during the movement $\vec{M}$:

$$\vec{P}(\vec{M}) = \sum_i^N w_{i\vec{M}} \vec{C}_i \quad (1)$$

where

$$w_{i\vec{M}} = F(d_{i\vec{M}}) \quad (2)$$

The steps in this computation are illustrated in Fig. 2.

Figure 3 shows neuronal population vectors for 8 arm movement directions calculated from contributions of 241 directionally tuned cells.

There are three basic attributes of the population vector: (a) its variable error or *precision*

(i.e., how much its direction varies across repeated calculations), (b) its constant error or *accuracy* (i.e., how much its direction differs from the direction of the movement to be predicted, namely, the angle between $\vec{P}(\vec{M})$ and $\vec{M}$), and (c) its *length* (related to the instantaneous velocity of the movement). Hence, when the population vector is integrated over time, it yields estimates of movement trajectories (i.e., position).

The two components in the calculation of the population vector include the *tuning function* and the *preferred direction*.

Tuning Function

Motor directional tuning is widespread in the brain (Mahan and Georgopoulos 2013). The tuning function $d_{i\vec{M}}$ is unimodal of potentially various forms. It is typically determined empirically by fitting experimental data. A common directional tuning function is the cosine function:

$$d_{i\vec{M}} = a + b \cos \theta_{\vec{C}_i \vec{M}} \quad (3)$$

where $\cos \theta_{\vec{C}_i \vec{M}}$ is the angle between the cell's preferred direction and the direction of the movement and a and b are regression coefficients. A similar tuning function is the power function

$$d'_{i\vec{M}} = ce^{k \cos \theta_{\vec{C}_i \vec{M}}} \quad (4)$$

This function allows for variation in the tuning width and thus is more versatile. Other tuning functions (e.g., Gaussian) are possible.

Given a neuronal population composed of directionally tuned cells, the question is what kind of scalar multiplier $F(d_{i\vec{M}})$ to use as a weight for the preferred direction. Three functions are commonly used:

$$F(d_{i\vec{M}}) = d_{i\vec{M}} \quad (5)$$

$$F(d_{i\vec{M}}) = d_{i\vec{M}} - d_{i\vec{M}} \quad (6)$$

Neuronal Population Vector, Fig. 1

Directional tuning and preferred direction. The *top panel* illustrates the orderly variation of the neural discharge of a single cell in the motor cortex of a monkey during arm movements in eight directions (five trials per direction). The average discharge rate (*filled circles, ±SEM*) is plotted in the *bottom panel* with a fitted cosine curve, with the preferred direction at the peak of the fitted curve. The ambiguity of the curve with respect to other movement directions is indicated by the *red horizontal line* at a given discharge rate: the line crosses the curve at two symmetric points corresponding to two different movement directions (*blue arrows*). This ambiguity points to the need for a unique, unambiguous coding of movement direction by a neuronal population.

T target onset, *Imp/s* impulses per second. Tics on the abscissa indicate 100 ms intervals. (Adapted from Georgopoulos et al. 1982; reproduced with permission by the publisher)

Neuronal Population Vector, Fig. 2

Schematic illustration of the population vector coding procedure

Neuronal Population Vector, Fig. 3 Accurate coding of eight movement directions by the population vector computed from the discharge rates of 241 neurons recorded in the motor cortex. Each one of the eight clusters consists of (a) the weighted preferred directions of the 241 cells

(solid lines) and (b) the calculated neuronal population vector (dotted arrow). The arrows in the center diagram indicate the direction of the instructed movement. (Adapted from Georgopoulos et al. 1983 with permission by the publisher)

$$F(d_{i\vec{M}}) = \frac{d_{i\vec{M}} - d_{i\vec{M}}}{d_{i\vec{M}}} \quad (7)$$

where $\bar{d}_{i\vec{M}}$ is the mean discharge rate, over all movement directions. Formally, the same functions can be used by substituting the observed $d_{i\vec{M}}$ by its estimated value $t_{i\vec{M}}$ from the corresponding tuning equation.

Preferred Direction

The preferred direction is the direction at the peak of the tuning curve. When calculating the population vector, the empirically calculated preferred direction is most frequently used. Alternatively, the distribution of the preferred directions can be optimized (to approach a uniform distribution) by taking into account the trial-to-trial variability in discharge rate (Salinas and Abbott 1994). This yields an *optimal linear estimator* for the population vector.

Applications

The neuronal population vector has been used extensively in various applications, including the

coding of the direction of arm movement in the monkey (Georgopoulos et al. 1986, 1988), the coding of direction of movement in the cockroach (Levi and Camhi 2000) and the leech (Lewis and Kristan 1998), the coding of prey motion direction in the dragonfly (Gonzalez-Bellido et al. 2013), the coding of faces in the inferotemporal cortex (Young and Yamane 1992), and the coding of mental tracing (Crowe et al. 2005; Gourtzelidis et al. 2005). As a measure to read out time-varying directional information, the population vector has been successfully used to visualize neural processing in mental rotation (Georgopoulos et al. 1989, 1993) and memory scanning (Pellizzer et al. 1995). One powerful application has been in neuroprosthetics, where neural activity recorded from the motor cortex of a tetraplegic woman was used to calculate instantaneous population vectors by which the subject controlled a prosthetic arm for feeding and playing (Collinger et al. 2013; Courtine et al. 2013).

Definition

Dependence of neuronal function on glial cells and vice versa, which consists of the interplay of potentially multiple signals that can be both of neuronal and of glial origin. This interplay may be facilitated by the specific arrangement of neurons versus glia in different brain areas and occurs on time scales extending from milliseconds to months, as well as on spatial scales ranging from subcellular and synaptic levels to those of networks and whole-brain structures.

Detailed description

Most animals share the ability to move in response to external stimuli, which results from having developed complex neural structures that allow for sophisticated processing of sensory information. From a phylogenetic perspective, as the nervous system changed from a simple net-like structure, such as in jellyfish (*Cnidara*), to condensed ganglia and centralized brains – starting with flat interstitial worms (*Acoelomorpha*) up to mammals (*Chordata*) – a new cell type could be recognized in morphological studies: glial cells (Hartline 2011; Laming et al. 2000). The importance of this new cell type for a functional brain is arguably reflected by the increase in the relative number of glial cells during evolution: there are roughly equal numbers of glial cells and neurons in mammals (Herculano-Houzel 2014) whereas, by contrast, glia constitutes only 10% of invertebrate neural cells in *Drosophila* or *C. elegans* (Hartline 2011; Bullock and Horridge 1965).

It is currently unknown whether glial cells from different clades share similar functions: the molecular, morphological, and physiological identity of glial cells across and within clades indeed remains a topic of active investigation (Hartline 2011). In the mammalian brain, the most numerous glial cells appear to fall into two categories: (i) macroglia, which is prominently constituted of oligodendrocytes and astrocytes and (ii) microglia (Lawson et al. 1990; Pelvig et al. 2008). Significantly, despite their different developmental origin – macroglia originating

from the embryonic ectoderm while microglia deriving from the mesoderm – both cell types share a common feature: that is the physical proximity to neurons by an elaborated branched anatomy that interweaves with neural processes (Kettenmann and Ransom 2013). This feature can be regarded as the teleological evidence of the purpose of glia for being an integral part of both the structure and function of neural networks of the mammalian brain.

Oligodendrocytes, for example, are responsible for myelination of axons, which is essential for their trophic support to attain long lengths while allowing for evolved organisms, like mammals and vertebrates in general, to achieve great sizes (Nave 2010). At the same time, myelination provides axons with high membrane electrical resistance and low capacitance, which prevents current loss and enables rapid and efficient conduction of action potentials – a prerogative of complex nervous systems to operate quickly and efficiently (Zalc and Colman 2000). As nervous systems increase in complexity, and this complexity correlates with the increasing sophistication of neurological function, a trend in increased complexity is also observed for astrocytes (Verkhratsky and Nedergaard 2016). Humans and primates indeed possess astrocytes that are larger and more branched than rodent astrocytes, with human's astrocytes generally being the largest (Oberheim et al. 2009). In agreement with this trend, if we graft human astrocytes in mice, we get animals that show enhanced learning and memory capabilities (Han et al. 2013). Finally, microglia, too, can be framed within the evolutionary perspective, in connection with the appearance of compact neural masses and the increased demand thereby of specialized phagocytic and immune functions, including mechanisms of neural protection (Pósfai et al. 2019). Remarkably, microglia invades the neural tube during embryogenesis before epithelial cells, neurons, and macroglia, being in the ideal position to regulate angiogenesis as well as neuro- and gliogenesis. It is now emerging that such regulation could extend beyond embryonic life as microglia can promote the formation and dismantling of functional neuron-glial networks by axon reorganization during

development and by regulation of genesis and pruning of synapses in the mature brain (Pósfai et al. 2019).

Although lagging behind classical computational neuroscience, theoretical and computational approaches are beginning to emerge to characterize different aspects of neuron-glial interactions (De Pittà and Berry 2019a). This chapter aims to provide essential knowledge on neuron-glial interactions in the mammalian brain, leveraging on computational studies that focus on structure (anatomy) and function (physiology) of such interactions in the healthy brain. Although our understanding of the need of neuron-glial interactions in the brain is still at its infancy, being mostly based on predictions that await for experimental validation, simple general modeling arguments borrowed from control theory are introduced to support the importance of including such interactions in traditional neuron-based modeling paradigms.

Anatomy of Neuron-Glial Interactions

Myelination of Axons by Oligodendrocytes

Myelination by oligodendrocytes and axon growth seem to be entirely interdependent since there are direct relationships among the age at which axons are myelinated, their final diameter in the adult, and the development of the associated oligodendrocytes (Butt 2013). Accordingly, oligodendrocytes and their axons should be considered together as functional units rather than separate functional entities. Myelinated axons can thus be thought to be functionally specialized since internodes provided by myelinic ensheathing and nodes of Ranvier develop in a concerted fashion to fulfill specific computational tasks (Tomassy et al. 2016; Hughes et al. 2018).

Electrical cable theory (FitzHugh 1962; Goldman and Albus 1968; Moore et al. 1978; Waxman 1980; Richardson et al. 2000) predicts that regulation of myelin thickness, internode length, and node geometry by oligodendrocytes (Ullén 2009; Fields 2008; Arancibia-Carcamo et al. 2017) could account for fine-tuning of action potential (AP) shape and conduction velocity

(Kimura and Itami 2009; Tomassy et al. 2014; Ford et al. 2015; Hughes et al. 2018) with important functional consequences. For instance, variations of internodal length associated with axon diameter dictate the extent of co-activation of nodal Na^+ with low-threshold K^+ channels.

In turn, a triaxial cable model of myelinated axons in sound processing circuits reveals how the synchronous activation of these channels may account for large, fast-rising and brief APs, differentiating axons that can propagate APs at high rates, and that belong to neurons that encode for high-frequency sounds, from axons that cannot, and instead depart from neurons that respond to low-frequency sounds (Halter and Clark Jr 1991; Ford et al. 2015). In those circuits, adjustments of internodal length may also occur in close register with nodal diameter, crucially setting the timing of AP arrival at synaptic terminals, which, in turn, underpins precise binaural processing of temporal information for sound localization (Carr and Konishi 1990; Carr et al. 2001; Carr and Soares 2002; McAlpine and Grothe 2003; Seidl et al. 2010; Ford et al. 2015). Together with delays induced by the AP-generation dynamics (Fourcaud-Trocmé et al. 2003) and those rising from synaptic processing (Markram et al. 1997), axonal conduction delays due to myelination by oligodendrocytes are an important property of neural interactions, which may induce a wealth of dynamical states with different spatiotemporal properties and domains of multistability that could serve different computational purposes (Roxin et al. 2005; Roxin and Montbrió 2011).

Müller Glia in the Retina

Formation of axon-myelin units by oligodendrocytes to fulfill specific functional tasks is only one of the possibly many cases of how neuronal structures and glial cells' morphology develop in a tight association. Another example is the retina of the vertebrate eye. Notably, this structure is inverted with respect to its optical function so that light must pass through several tissue layers before reaching the light-detecting photoreceptor cells. In doing so, projected images on the retina would rapidly deteriorate due to light scattering by optical and geometrical inhomogeneities of

those different layers if it were not for specific properties and arrangement of structures and cell assemblies of the retina that ensure correct vision (Tuchin 2000; Masland 2001). In this scenario, the most common type of retinal glial cells, known as Müller cells, shows a characteristic cylindrical, funnel-like shape that spans the entire thickness of the retina and functions as the waveguide of visible light from the retinal surface to the photoreceptor cell layer (Franze et al. 2007). Numerical solution of the Helmholtz equation in a model of retinal tissue suggests that this property of Müller cells to guide light crucially enhances vision acuity since, like fiber optics that penetrate through the retinal layers, these cells can propagate light straight down to the photoreceptor cell they associate with (Labin and Ribak 2010). In particular, every mammalian Müller cell is coupled, on average, to one cone photoreceptor cell, that is responsible for sharp seeing under daylight conditions (i.e., photopic vision), plus several rod photoreceptor cells, serving low-light-level, night (scotopic) vision (Reichenbach and Robinson 1995). Remarkably, the spectrum of light transmitted through Müller cells, derived from theoretical calculations based on data of the human parafoveal retina, matches almost perfectly the absorption spectra of the medium- and long-wavelength human cone photoreceptors, predicting a gain in photon absorption by a factor of ~ 7.5 by these photoreceptors, and by a factor of by human short-wavelength cones (Labin et al. 2014). At the same time, the spectrum of light leaking outside Müller cells matches the absorption spectrum of human rod photoreceptors. In this fashion, Müller cells provide a mechanism to improve cone-mediated photopic vision, with minimal interference with rod-mediated scotopic vision since not only they guide light of relevant wavelengths for cone visual pigments directly towards cones but also they allow for light of wavelengths more suitable for rod vision to leak to surrounding rods (Labin et al. 2014).

Astrocytes and Regulation of Volume Transmission

Broadly speaking, the factors underpinning morphogenesis of neuronal structures in tight

association with glial cells remain poorly understood, although they are thought to encompass a combination of transcriptional programs and a battery of molecular signals that seem to be regulated both developmentally and regionally, in a cell-specific manner (Jadhav et al. 2009; Eroglu and Barres 2010; Götz 2013; Stassart et al. 2013). A paramount example of this complex combination of factors is provided by astrocytes, which are glial cells predominantly found in the cortex and hippocampus and are recognized as critical regulators of the neuronal connectome in those brain regions (Fields et al. 2015). In the postnatal, developing brain, astrocytes are indeed found in spatially distinct domains and express domain-specific genes that are needed to support the formation of specific neural circuits and neuronal subtypes (Molofsky et al. 2014). On the other hand, they also secrete a variety of molecules that regulate with spatiotemporal specificity all stages of the genesis of functional neural circuits, such as the establishment of immature (silent) synapses between axon and dendrites, the conversion of these silent synapses into active ones by insertion (and maintenance) of functional receptors, and the elimination of excess synapses and synaptic pruning to refine connections in neural circuits (Allen 2013; Clarke and Barres 2013). Remarkably, this close relationship between astrocytes and synapses continues in the adult brain, with the processes of astrocytes that infiltrate into the neuropil and wrap themselves around synapses in a seemingly nonrandom fashion (Reichenbach et al. 2010), engaging in a multitude of signals (Fig. 1), with figures approaching 20–180 thousand synapses contacted by a single astrocyte in the rodent brain (Bushong et al. 2002), but ~270 thousand to 2 million synapses per astrocyte in the human brain (Oberheim et al. 2009). What are the possible functional purposes of this ensheathing?

One obvious possibility is that processes of astrocytes are strategically positioned at synaptic loci to act as physical barriers that constrain and regulate extracellular diffusion of neurotransmitters (Ventura and Harris 1999). With this regard, a realistic reconstruction of the extracellular space (ECS) in between astrocytic processes and glutamatergic synapses of the hippocampus – one of the brain structures where the

morphological association of astrocytes with synapses has been best-characterized (Seifert and Steinhäuser 2017) – revealed a strong anisotropy for glutamate diffusivity, directly imputable to the peculiar arrangement of astrocytes with the surrounding neuropil (Kinney et al. 2013). This anisotropy ensues from the nonuniform width of ECS, which forms thin sheets in the periastrcytic space and grows wider into tunnels in correspondence with synapses and axons. Monte Carlo diffusion simulations show that the diffusion rate of glutamate through the neuropil critically depends on the proportion of sheets versus tunnels, since the smaller median extracellular width of astrocyte-delimited sheets poses a diffusion barrier to glutamate molecules, corralling them into tunnels which favor their diffusion instead (Kinney et al. 2013). This scenario, along with the expression of glutamate transporters by perisynaptic astrocytic processes (Danbolt et al. 2002), would ultimately provide a mechanism to canalize glutamate to specific targets while keeping low the risk of excitotoxicity brought forth by the fact that glutamate is not normally destroyed in the ECS (Rothstein et al. 1996).

The degree of astrocytic ensheathing at glutamatergic synapses indeed directly dictates the rate of glutamate uptake by glial transporters – the primary mechanism of glutamate uptake in the adult brain (Danbolt 2001) – regulating the time course of this neurotransmitter in the synaptic cleft and its potential to spill out to neighboring synapses (Clements 1996). Remarkably, the degree of astrocyte ensheathment seems inversely correlated with the size of dendritic spines (Medvedev et al. 2014), suggesting that, in agreement with independent theoretical arguments (Barbour 2001), smaller synapses are best sealed by astrocytic processes to minimize glutamate spillover. On the contrary, glutamate spillover could occur at larger synapses, for which the degree of astrocytic ensheathing is only up to approximately one-third of their perimeter (Ventura and Harris 1999). To the extent that thin-spine versus large-spine synapses can respectively be assimilated to silent versus functional synapses (Matsuzaki et al. 2001), the latter possibility hints a crucial role of astrocytic ensheathing

Physiology of Neuron-Glial Interactions

General Modeling Framework

If the reciprocal disposition of neurons with respect to glial cells in the brain fulfills essential anatomical constraints for their interaction, the existence of two-way dynamic signaling, from neurons to glia and vice versa, accounts for the physiology of this interaction. With this regard, a common framework to model networks of interacting neurons (Ermentrout and Terman 2010) may be borrowed to illustrate essential functional consequences of neuron-glial interactions. Denoting by $\mathbf{x}$ and γ the activities of neuronal and glial interacting ensembles, respectively, defined as column vectors in $\mathbb{R}^N$ and $\mathbb{R}^G$, then the glial activity can generally be described by

$$\tau_\gamma \dot{\gamma} = -\gamma + \mathcal{F}_\gamma(\mathbf{b}_\gamma + \mathbf{I}_\gamma(\mathbf{x}, \gamma)) \quad (1)$$

where $\mathcal{F}_\gamma : \mathbb{R}^g \rightarrow \mathbb{R}^G$ ($g \geq G$) represents the glial input-output transfer function. The argument of this function – that is the input to glia – consists of (i) an external bias $\mathbf{b}_\gamma \in \mathbb{R}^g$ coming, for example, from brain areas away from the neuron-glial ensemble under consideration and of (ii) a recurrent input $\mathbf{I}_\gamma(\mathbf{x}, \gamma) : \mathbb{R}^{N+G} \rightarrow \mathbb{R}^g$ due to neuronal and glial activities within the ensemble itself. The physiological correlate of γ , along with the choice of $\mathcal{F}_\gamma$ and $\mathbf{I}_\gamma$, depend on what “glial activity” refers to, and it will be clarified below. Similarly, without specifying for now what “neuronal activity” is, an equation analogous to 1 may be written for $\mathbf{x}$, i.e.,

$$\tau_x \dot{\mathbf{x}} = -\mathbf{x} + \mathcal{F}_x(\mathbf{b}_x + \mathbf{I}_x(\mathbf{x}, \gamma)) \quad (2)$$

where $\mathcal{F}_x : \mathbb{R}^n \rightarrow \mathbb{R}^N$, $\mathbf{b}_x \in \mathbb{R}^n$ and $\mathbf{I}_x(\mathbf{x}, \gamma) : \mathbb{R}^{N+G} \rightarrow \mathbb{R}^n$ ($n \geq N$). In the previous equations, what the “activities” $\mathbf{x}$ and γ refer to are suitable measurables of neuronal and glial physiology, respectively. Membrane voltage, firing rate, and synaptically released neurotransmitters are typical examples of such measurables for neurons. For glia instead, cytosolic calcium is probably the most hitherto studied readout of these cells in response to neuronal stimulation, yet possibly not the only one, since other intracellular ions like Na^+ , K^+ , H^+ , Cl^- , or HCO_3^- , along with a whole cassette of molecules involved in the genesis of calcium signaling, could also be indicators of glial stimulation (De Pittà and Berry 2019b). At the same time, the notion of neuronal and glial ensembles is somehow broad. We may encompass by this notion brain structures, including whole networks of neurons and glia, or components of these networks, for example, myelinated axons with their oligodendrocytes, or groups of synapses with their perisynaptic glial processes (of astrocytic or microglial origin). In this context, the emerging notion that calcium homeostasis, as well as the homeostasis of other ions and macromolecules, could be compartmented within the glial cell’s morphology (Breslin et al. 2018, see also ▶ “Intracellular Calcium Signals in Astrocytes, Computational Modeling of”), allows using equations akin to 1 and 2 to model dynamics of neuron-glial interactions at multiple spatial scales, where scale-specific aspects of such interactions may be lumped into the choice of the transfer functions $\mathcal{F}_i$ (with $i = \mathbf{x}, \gamma$), their input arguments $\mathbf{b}_i$, $\mathbf{I}_i$, and ultimately, the components of the activity vectors $\mathbf{x}$ and γ .

The functions $\mathcal{F}_i$ and $\mathbf{I}_i$ are generally nonlinear with respect to their input variables. This hinders

Neuron-Glial Interactions, Fig. 1 (continued) SERCA (sarco)endoplasmic reticulum Ca^{2+} -ATPase, *SNAT* Na^+ -coupled neutral amino acid transporter, *SVCT2* Na^+ -dependent vitamin C transporter 2, *TACE* TNF α -converting enzyme, *TNF α* (*TNFR*) tumor necrosis

any attempt to look beyond the general form of Eqs. 1 and 2 to fathom neuron-glial interactions with the aim to derive different mechanisms of action and function that could be shared (or not) by different pathways of interaction. The situation greatly simplifies if we limit our analysis to the first order expansion of $\mathbf{I}_i$ around the resting point $(\mathbf{x}_0, \gamma_0)$. In this case, Eqs. 1 and 2 become

$$\tau_\gamma \dot{\gamma} \approx -\gamma + \mathcal{F}_\gamma(\mathbf{b}_{0_\gamma} + \mathbf{W}_\mathbf{x}(\mathbf{x} - \mathbf{x}_0) + \mathbf{J}_\gamma(\gamma - \gamma_0)) \quad (3)$$

$$\tau_\gamma \dot{\mathbf{x}} \approx -\mathbf{x} + \mathcal{F}_\mathbf{x}(\mathbf{b}_{0_\mathbf{x}} + \mathbf{J}_\mathbf{x}(\mathbf{x} - \mathbf{x}_0) + \mathbf{W}_\gamma(\gamma - \gamma_0)) \quad (4)$$

where, for $i = \mathbf{x}, \gamma$, $\mathbf{b}_{0_i} = \mathbf{b}_i + \mathbf{I}_i(\mathbf{x}_0, \gamma_0)$, $\mathbf{J}_i = (D_i \mathbf{I}_i(i, j))_{(\mathbf{x}_0, \gamma_0)}$ and $\mathbf{W}_i = (D_j \mathbf{I}_i(i, j))_{(\mathbf{x}_0, \gamma_0)}$, with $D_\mathbf{x} \mathbf{I}_i = \left(\frac{\partial \mathbf{I}_i}{\partial x_0}, \dots, \frac{\partial \mathbf{I}_i}{\partial x_{N-1}} \right)$ and $D_\gamma \mathbf{I}_i = \left(\frac{\partial \mathbf{I}_i}{\partial \gamma_0}, \dots, \frac{\partial \mathbf{I}_i}{\partial \gamma_{G-1}} \right)$. In this way, it is possible to distinguish between different contributions to the evolution of neuronal (glial) activity by $\mathcal{F}_\mathbf{x}$ ($\mathcal{F}_\gamma$), in particular separating those that are due to neuronal (glial) elements weighted by the matrix $\mathbf{J}_\mathbf{x}$ ($\mathbf{J}_\gamma$) from those that result instead from glial (neuronal) elements and that are weighted by the matrix $\mathbf{W}_\mathbf{x}$ ($\mathbf{W}_\gamma$). Because matrices $\mathbf{J}_\mathbf{x}$, $\mathbf{J}_\gamma$ lump couplings of neuronal (respectively glial) activities with themselves, whereas matrices $\mathbf{W}_\mathbf{x}$, $\mathbf{W}_\gamma$ couple neuronal activities with glial activities and vice versa, we hereafter refer to them as *homotypic* and *heterotypic* weight (or connection) matrices, respectively.

The input terms associated with heterotypic connections represent the actual interaction pathways, for signaling from neurons to glia ($\mathbf{W}_\mathbf{x}\mathbf{x}$), and vice versa, from glia to neurons ($\mathbf{W}_\gamma\gamma$). In several practical scenarios (Fig. 2), this signaling is mediated by specific molecules or ions, that may themselves be regarded as measures of neuronal (glial) activity, or can alternatively be expressed in terms of $\mathbf{x}$ (respectively γ). Consider, for example, synaptically evoked gliotransmission (Araque et al. 2014, see also *yellow* and *red* pathways in Fig. 1). This form of neuron-glial interaction consists of the

activity-dependent release of neuroactive molecules from astrocytes, including neurotransmitters like glutamate, ATP, GABA, or D-serine that, for their glial origin, are termed “gliotransmitters.” The release can be triggered by synaptically-released neurotransmitters and be mediated by different intracellular pathways that often associate with transient calcium signaling in the astrocyte (Savtchouk and Volterra 2018). In turn, gliotransmitters can modulate synaptic transmission both presynaptically – binding to receptors that regulate the probability of release of neurotransmitter-containing synaptic vesicles – and postsynaptically, gating receptors/ion channels that control neuronal depolarization (and excitability). In this description, synaptically-released neurotransmitters mediate neuron-to-astrocyte signaling, whereas gliotransmitters are responsible for the astrocyte-to-neuron signaling. To couple these two signaling pathways by the above framework, however, biophysical correlates for their functional interdependence must also be explored. For the dependence of gliotransmitter release on synaptic release, at least at first approximation, gliotransmitter release is expected to rise with synaptic neurotransmitter release (Araque et al. 2014). For the dependence of this latter on gliotransmitter release instead, the reasoning is as follows: (i) activation of presynaptic receptors by gliotransmitters increases with gliotransmitter release; in turn (ii) modulation of intrasynaptic Ca^{2+} , which is linked with p – the synaptic release probability (► “Biophysical Models of Calcium-Dependent Exocytosis”) – correlates with the degree of receptor activation by gliotransmitters; and (iii) synaptic release is proportional to p . In this fashion, the simplest scenario sees γ in the above equations reducing to a scalar variable that is associated with the fraction of gliotransmitter-activated receptors, whereas p replaces $\mathbf{x}$. Then, assuming that at rest $\gamma_0 = 0$, $p_0 = p^* > 0$, the simplest model for the presynaptic pathway of synaptically-evoked gliotransmission (Fig. 2a) derived by Eqs. 3 and 4 reads

$$\tau_\gamma \dot{\gamma} = -\gamma + \mathcal{F}_\gamma(b_{\gamma_0} + W_\gamma p + J_\gamma \gamma) \quad (5)$$

Neuron-Glial Interactions, Fig. 2 Feedback and feedforward pathways in neuron-glial interactions. (a) Pre-synaptic pathway of gliotransmission stimulated by presynaptically released neurotransmitters; (b) postsynaptic pathway of gliotransmission stimulated by presynaptically released neurotransmitters; (c) presynaptic pathway of gliotransmission triggered by postsynaptic endocannabinoid release; (d) postsynaptic pathway of

gliotransmission mediated by postsynaptic endocannabinoid release; (e) modulation of glutamatergic gliotransmission by $TNF\alpha$. (f) K^+ buffering and regulation of neuronal activity; (g) glutamate-glutamine cycle (GCC); (h) astrocyte-to-neuron lactate shuttle (ANLS); (i) extracellular pH homeostasis; (j) glutathione synthesis; (k) neurovascular coupling; and (l) gliotransmission mediated by postsynaptic endocannabinoid release. $[Ca^{2+}]_i$ intracellular

$$\tau_p \dot{p} = p^* - p + \mathcal{F}_p((1 - J_p)p^* + J_p p + W_p \gamma) \quad (6)$$

where b_{γ_0} may or not be present, depending on the presence or not of other mechanisms triggering gliotransmitter release that are independent of stimulation of the very synapse modulated by gliotransmission, e.g., microglia-mediated Ca^{2+} signaling in the astrocyte (Pascual et al. 2011). The homotypic weight J_γ accounts for the theoretically-predicted phenomenon of gliotransmitter-triggered gliotransmission (Larter and Craig 2005), whereas the homotypic weight J_p can generally be accounted by mechanisms of short-term plasticity (► “Short-Term Plasticity, Biophysical Models”). With regard to the heterotypic weights instead, it generally is $W_\gamma > 0$ regardless of the nature of synaptic neurotransmitters, that is both excitatory and inhibitory neurotransmitters are excitatory for glial activation (Durkee et al. 2019). The sign of W_p instead is dependent on the nature of gliotransmission, which can either decrease or increase synaptic release (De Pittà et al. 2015). Remarkably, while the sign of W_p is set by functional and anatomical features of synapse-astrocyte ensembles (De Pittà 2019), the further possibility that the polarity of gliotransmission could also depend on specific patterns of activity (Covelo and Araque 2018) can be accounted by the choice of $\mathcal{F}_p$.

If we aim for a more general understanding of gliotransmission on synaptic transmission, it is then useful to think of the efficacy (or strength) of synaptic transmission in terms of the product $w = p \cdot q$, where q is the probability of activation of postsynaptic receptors by the presynaptically-released neurotransmitter. In this context then, choosing $\mathbf{x} = (p, q)^T$ with $q_0 = q^* > 0$ results in the system of three equations in the general form of

$$\begin{aligned} \tau_\gamma \dot{\gamma} &= -\gamma \\ &+ \mathcal{F}_\gamma(b_{\gamma_0} + W_\gamma^{(p)} p + W_\gamma^{(q)} q + J_\gamma \gamma) \end{aligned} \quad (7)$$

$$\begin{aligned} \tau_p \dot{p} &= p^* - p + \mathcal{F}_p((1 - J_p)p^* - W_p^{(q)} q^* \\ &+ J_p p + W_p^{(q)} q + W_p^{(\gamma)} \gamma) \end{aligned} \quad (8)$$

$$\begin{aligned} \tau_q \dot{q} &= q^* - q + \mathcal{F}_q(-W_q^{(p)} p^* + (1 - J_q)q^* \\ &+ W_q^{(p)} p + J_q q + W_q^{(\gamma)} \gamma) \end{aligned} \quad (9)$$

The coupling factors J_q , $W_\gamma^{(q)}$, $W_p^{(q)}$, and $W_p^{(\gamma)}$ ensue from the consideration of endocannabinoid signaling, which may retrogradely suppress synaptic activity while, at the same time, triggering Ca^{2+} -dependent gliotransmitter release from the astrocyte (Navarrete et al. 2014). In particular, because this signaling pathway depends on postsynaptic depolarization (v_m), and this latter is dependent on incoming synaptic activity by w , it is safe to assume that endocannabinoid signaling can be expressed in terms of p and q by a proper choice of the transfer functions $\mathcal{F}_\gamma$, $\mathcal{F}_p$, and $\mathcal{F}_q$ and their input arguments I_γ , I_p , and I_q in the original Eqs. 1 and 2 (Figs. 2c, d). On the other hand, when no retrograde signaling (including endocannabinoid) is taken into account, then $J_q = 0$ and also $W_\gamma^{(q)} = W_p^{(q)} = W_p^{(\gamma)} = 0$, allowing for a significant simplification of the above equations. Even more so if the analysis is restricted to the sole postsynaptic pathway of gliotransmission without considering any mechanism of short-term plasticity, for which, synaptic dynamics reduces to $\tau_p \dot{p} = p^* - p$ and $\tau_q \dot{q} = q^* - q + \mathcal{F}_q(-W_q^{(p)} p^* + q^* + W_q^{(p)} p + W_q^{(\gamma)} \gamma)$ with γ being described by an equation like 5. In this scenario, gliotransmission release (γ) becomes uncoupled from q (but not the opposite), and the dynamics of both γ and q is driven by p (Fig. 2b). The resulting $q(t)$ can essentially be expressed in

terms of $p(t)$ but, differently from a stand-alone synapse, the effect of p on q (and thus on v_m) also incorporates, possibly in a nonlinear fashion, the effect of gliotransmission. Remarkably, this scenario could underpin several examples of neuron-glia interactions such as: (i) regulation of long-term synaptic plasticity by D-serine released from astrocytes in the hippocampus, hypothalamus, and the cortex (Bains and Oliet 2007); (ii) AMPA receptor internalization in the cerebellum by D-serine originating from Bergmann glial cells (Kakegawa et al. 2011); (iii) AMPA receptor insertion by adrenergic stimulation of ATP release from hypothalamic astrocytes (Gordon et al. 2005); (iv) modulation of AMPA and GABA receptor trafficking by astrocytic TNF α (Stellwagen et al. 2005); and (v) slow inward and outward currents (SICs and SOC s) respectively mediated by glutamate and GABA from astrocytes (Fellin et al. 2004; Le Meur et al. 2012).

The distinction between homotypic versus heterotypic couplings brought forth by Eqs. 3 and 4 allows the analysis of otherwise complex neuron-glia interactions in terms of combinations (to the first-order approximation) of feedback and feedforward mechanisms, which can conveniently be illustrated by functional diagrams such as those in Fig. 2. Furthermore, consideration of these diagrams can help classify different pathways of interaction between neurons and glia based on their coupling mechanisms. In this fashion, activity-dependent presynaptic pathways of gliotransmission can all be assimilated to a feedback mechanism on synaptic release, which can be either positive or negative, depending, as previously stated, on the nature of astrocyte-synapse coupling and synaptic dynamics (Fig. 2a). Conversely, the postsynaptic pathway of gliotransmission is tantamount to a feedforward mechanism on postsynaptic membrane depolarization, which can also be positive or negative, depending on the gliotransmitter type and whether gliotransmission promotes receptor internalization or insertion (Fig. 2b). Consideration of endocannabinoid signaling does not change the essence of these mechanisms, except for the fact that a further intermediate processing stage must be taken into account for the regulation of

endocannabinoid release from postsynaptic terminals (Fig. 2c). Nonetheless, differently from other pathways of synaptic transmission, in this latter case, postsynaptic pathways of gliotransmission may also feedback on endocannabinoid release since this process depends on postsynaptic depolarization (Fig. 2d). On the other hand, glutamatergic gliotransmission could also contemplate the existence of positive feedback on the astrocyte by its release of the cytokine TNF α (Fig. 2e). Constitutive extracellular levels of this cytokine ([TNF α] $_e$) may indeed promote glutamate release from astrocytes but can also regulate the production of TNF α by these cells (Santello et al. 2011). Furthermore, microglia could also regulate glutamatergic gliotransmission, releasing ATP as part of their immune response, and thereby promoting Ca $^{2+}$ -dependent glutamate release from astrocytes (Pascual et al. 2011). Alternatively, extracellular glutamate ([Glu] $_e$) may trigger the release of TNF α from microglia, which could stimulate the further release of glutamate from astrocytes in, yet another, positive feedback fashion (Bezzi et al. 2001).

Potassium ion homeostasis is also involved in multiple feedback pathways mediated by glia (Fig. 2f). Neuronal activity results in local accumulations of extracellular K $^{+}$ ([K $^{+}$] $_e$) that may promptly be abated by spatial buffering by glia (Kofuji and Newman 2004). Significantly, synaptically evoked Ca $^{2+}$ signaling in astrocytes (*yellow pathway*) can also regulate [K $^{+}$] $_e$ to modulate both spontaneous synaptic release at excitatory synapses and neuronal firing (Wang et al. 2006). In the cerebellum, Ca $^{2+}$ -dependent K $^{+}$ uptake by Bergman glia can dramatically alter the firing dynamics of Purkinje cells (Wang et al. 2012b). At cortical axons instead (Fig. 2l), depolarization of myelinating oligodendrocytes following AP conduction is speculated (Debanne et al. 2011) to alter extracellular levels of K $^{+}$ and Na $^{+}$ locally, at nodes of Ranvier, thereby transiently promoting action potential generation which could speed up AP conduction by 10% (Yamazaki et al. 2007). On the other hand, astrocytes, too, could influence AP generation at nodes of Ranvier, specifically by increasing AP duration by Ca $^{2+}$ -dependent glutamate release, although the activity requirements

for this pathway are not known (Sasaki et al. 2011).

Very often, a signaling pathway or a biophysical process may be shared by different mechanisms of neuron-glial interactions. Extracellular glutamate and its uptake by astrocytes, for example, are key components of the so-called glutamate–glutamine cycle (GCC), as well as of the astrocyte-to-neuron lactate shuttle (ANLS) (see ► “Brain Energy Metabolism”). In the GCC (Fig. 2g), glutamate taken up by astrocytic transporters is converted into glutamine, which is transported back to neurons, where it is presumably reconverted to glutamate, thereby guaranteeing the supply of this neurotransmitter to sustain synaptic transmission (Xiang et al. 2003). In the ANLS instead (Fig. 2h), astrocytic lactate – ensuing from ATP demand to counteract intracellular Na^+ accumulation by glutamate uptake – is shuttled to neurons where it is converted to pyruvate, which is necessary for ATP synthesis by mitochondria, and thus it mediates a positive feedback loop that can sustain the energetic cost of prolonged neuronal firing activity (Allaman et al. 2011). Remarkably, both ANLS and GCC could also be integral components of other pathways of neuron-glial interactions. Lactate, for example, may also cover synaptic energy demand indirectly by triggering prostaglandin release from astrocytes, which, in turn, increases blood flow and thereby, glucose supply to neurons (Attwell et al. 2010). Alternatively, it could also operate as gliotransmitter (Tang et al. 2014). Glutamine produced by GCC, on the other hand, could also be a precursor of glutathione (GSH) in the synthesis of this latter by astrocytes (Fig. 2j), which is a key process in neuroprotection by glia. Neurons are also capable of synthesizing GSH from glutamate, but this is constrained by their intracellular availability of cysteine and glycine. Astrocytes can, however, backup on the availability of these two amino acids in neurons by releasing GSH, which is extracellularly cleaved to produce cysteinylglycine that neurons, in turn, cleave to supply cysteine and glycine to their intracellular resources (Dringen 2000). Finally, glutathione metabolism could also be linked with vitamin C (ascorbic acid) exchange between neurons and

glia as illustrated by the *brown pathway* in Fig. 1 (Castro et al. 2009; May 2012).

In several cases, neuron-glial interactions add to existing neuronal feedback mechanisms. Two examples, respectively, are the control of extracellular pH and the regulation of blood flow by astrocytes. Neuronal electrical activity results in extracellular alkalinization and intracellular acidification around neuronal cell walls, which can considerably alter neuronal excitability and synaptic currents (Deitmer and Rose 1996). This is put in place by a multitude of diverse mechanisms that rely on physiochemical buffers, metabolic reactions, and membrane transport systems within neurons and in the interstitial fluid that make extracellular and intracellular neuronal pH completely interdependent. On the other hand, intracellular pH of astrocytes is also dependent on extracellular pH, and astrocytes, akin to neurons, express a variety of transport and buffering mechanisms that make them capable of influencing H^+ homeostasis locally and brain-wide actively. By similar arguments, both neurons and glial cells require a constant supply of metabolites and chemical species by the bloodstream. Yet, they can regulate blood flow by the independent release of vasoactive signals (Attwell et al. 2010), as well as do so in interaction with each other by the other neuron-astrocyte interaction pathways hitherto presented.

The existence of feedback and feedforward pathways of interactions between neuronal and glial elements challenges traditional connectomics. We come to realize in fact that neurons are not merely connected by synapses but also by extracellular glial-mediated pathways. Moreover, for some of these pathways, like at synapses where signal transmission is traditionally assumed to occur in one direction only – from the presynaptic terminal to the postsynaptic one – this directionality is replaced by a neuron-glial signaling network that is inherently recurrent. Recurrent connections are essential in network theory since they can control the stability of network activity and its robustness to noise. Accordingly, the model of an autaptic neuronal oscillator may conveniently be adopted to get a flavor of the potential relevance of glia-mediated synaptic recurrence on neuronal firing

(Volman et al. 2007). The autaptic oscillator consists of an excitatory neuron that exhibits periodic firing employing self-synapses (i.e., autapses) whose strength critically controls the neuron's firing rate and its stability (Seung et al. 2000). In this fashion, when all autapses also stimulate the same astrocytic domain and are equally affected by release-decreasing gliotransmission ensuing from it, activity-dependent fluctuations of neuronal firing rate emerge in phase opposition with astrocytic Ca^{2+} spikes (Volman et al. 2007). The mechanism would not be surprising per se if it were not for the fact that it can also be observed in the presence of irregular bursting by the autaptic neuron. The theory of autaptic oscillators (without astrocyte) predicts in fact that the positive feedback exerted by excitatory autapses on the neuron only allows this latter to maintain its firing rate at the onset of stimulation, or to increase it, ultimately reaching unrealistic (epileptiform) firing rates (Seung et al. 2000). This scenario is avoided in the presence of release-decreasing gliotransmission, however, because any self-amplifying increase of neuronal activity that could be triggered, for example, by a burst of APs, promotes gliotransmitter release from the astrocyte, which promptly counteracts the neuron's runaway by excitation by depressing autaptic transmission. In this fashion, the negative feedback exerted by gliotransmission on synapses competes with the positive autaptic feedback to prevent the neuron from persistently generating APs at high rates. Rather, the opposite happens, as prolonged periods of depressed synaptic excitation, consistent with the long-lasting effect of release-decreasing gliotransmission observed *in vitro* (Araque et al. 1998), substantially modify the firing statistics of the autaptic neuron, accounting for large interspike intervals. The ensuing neural bursting may accordingly be thought of as the alternation of APs with irregular periods of no activity and explains why the Gaussian distribution of interspike intervals otherwise observed for an autaptic neuron without astrocyte is instead heavy-tailed in the presence of gliotransmission (Volman et al. 2007).

Modulation of Neural Excitability

Two pathways for regulation of neuronal excitability by glia have hitherto been explored by

computational studies: one by glia-mediated control of K^+ homeostasis and the other by modulation of excitatory synapses by astrocytes. In the first case, the fact that cortical astrocytes, Müller glia in the retina, or Bergmann glia in the cerebellum, buffer extracellular K^+ redistributing it to sites of lower concentration, locally changes the resting membrane potential of neurons by the ► “Goldman-Hodgkin-Katz Equations” as well as the Nernst potential of individual ions (► “Nernst Equation”), thereby modulating the neuron's threshold for AP generation. This modulation can be crucial to set the tone of neuronal firing in healthy physiological conditions since blocking glial buffering could turn random firing maintained by random external stimulation into periodic bursting, and eventually lead to permanent spike inactivation (Bazhenov et al. 2004). Mechanistically, glial K^+ buffering can be by different combinations of passive and active transport systems, which, however, share an interplay between glial ATP-driven Na^+/K^+ pumps (NKPs) and Kir channels. Depending on neuronal activity, this interplay can mediate nontrivial positive feedback on neuronal firing, for example, promoting AP generation in conditions of low neuronal firing (Somjen et al. 2008) or turning regular spiking dynamics into bursting (Somjen et al. 2008; Øyehaug et al. 2012; Cui et al. 2018).

Control of neuronal firing by modulation of excitatory synaptic transmission by astrocytes could instead occur, in principle, both by pre- and postsynaptic pathways of gliotransmission, and intrasynaptically, by glutamate uptake by astrocytic transporters. In the first scenario, the rationale for modulation essentially follows that of Eqs. 7, 8 and 9, where Ca^{2+} -dependent gliotransmission could be triggered either by synaptically activated astrocytic metabotropic receptors (De Pittà and Brunel 2016) or by Na^+ influx into the astrocyte by glutamate transporters which in turn regulates Ca^{2+} influx into the astrocyte by $\text{Na}^+/\text{Ca}^{2+}$ -exchangers (Flanagan et al. 2018), though this latter possibility requires experimental validation. In the second scenario, detailed kinetic models of astrocytic transporters and AMPA and NMDA synaptic receptors suggest instead that control of glutamate clearance by astrocytic

transporters could modulate postsynaptic receptors' activation and desensitization thereby modulating the kinetics of postsynaptic current. This results in subtle changes in spike arrival timings and spike failures that modulate the firing pattern of the postsynaptic neuron (Allam et al. 2012).

Neuron-Glial Interactions in Neural Networks

The importance of uptake of neurotransmitters such as glutamate and GABA by astrocytes in setting the tone of neural network activity has only been partially explored in the framework of ► **"Neural Mass Action"** modeling, yet producing two interesting predictions (Garnier et al. 2016). First is the observation that a deficiency of GABA uptake by astrocytes increases the threshold for neuronal activation in a linear fashion. Second is the prediction that, in the presence of deficient astrocytic glutamate uptake, neural activity may either be reduced or enhanced or may display a transient of high activity before stabilizing around a new regime whose firing frequency is close to the one measured in the absence of astrocyte deficiency. Significantly, the somehow counterintuitive possibility that neural activity could decrease despite extracellular glutamate accumulation due to deficits in astrocytic uptake, may be observed only in the presence of sufficient interneuron hyperexcitability.

More generally, in the framework of neuronal network theory, modulation of neuronal excitability and synaptic transmission by glia is expected to modulate the balance of excitation (E) versus inhibition (I) with the potential to regulate network activity dramatically. This possibility follows by the analysis of the few available neuron-glia network models, which come in different flavors in terms of the combination of different E-I network configurations and different choices of neuronal (and synaptic) models and astrocytic signaling pathways (Savin et al. 2009; Ullah et al. 2009; Volman et al. 2013; Savtchenko and Rusakov 2014). Nonetheless, all these models eventually envisage an effect of glial signaling in terms of a modulation of synaptic drive, either at excitatory (Savin et al. 2009; Savtchenko and Rusakov 2014) or excitatory and inhibitory synapses (Ullah et al. 2009; Volman et al. 2013;

Garnier et al. 2016), which accounts for the emergence of variegated network activity. With this regard, a model by Ullah et al. (2009) considers the effect of astrocytic regulation of extracellular K^+ and Na^+ on firing dynamics of both excitatory and inhibitory neurons with voltage-dependent synaptic inputs. Accordingly, neuronal membrane potential dynamics depends on K^+ and Na^+ homeostasis regulated by astrocytes and so does the network's E-I balance. In this framework, brief (30 ms-long) step increases of E-to-E synaptic strength, which could loosely ensue from glial glutamate exocytosis, promote transient increases of neuronal firing, whose duration, however, depends on extracellular K^+ concentration (Ullah et al. 2009). In particular, for plausible non-pathological values of this concentration, the network could display transient episodes of persistent enhanced firing, which are reminiscent of persistent activity during UP states (Sanchez-Vives and McCormick 2000; Amzica et al. 2002; McCormick et al. 2003), as well as during delay periods of working memory tasks (Funahashi et al. 1989; Goldman-Rakic 1995).

Similar observations may also be made by other models which consider different scenarios of gliotransmission, such as short-term modulations of E-to-I synaptic connections by glutamatergic or purinergic gliotransmission (Savtchenko and Rusakov 2014), or homeostatic upregulation of excitation by glial $TNF\alpha$, although this latter scenario could also account for the emergence of paroxysmal activity in various pathological conditions (Volman et al. 2013). Significantly, these models identify in the spatial extent of gliotransmission a further key factor for the regulation of glia-mediated episodes of increased network activity, ranging from their frequency and duration (Volman et al. 2013) to the degree of network synchronization and the average firing rate of single neurons during their occurrence (Savtchenko and Rusakov 2014). With this regard, the transient depression of synapses within an astrocytic anatomical domain, which could mimic release-decreasing gliotransmission or temporary disruption of release-increasing gliotransmission, correlates with a decrease of neuronal firing and synchronization,

which is more significant for larger astrocytic domains (Savtchenko and Rusakov 2014).

Regulation of Synaptic Transmission and Plasticity

Modulation of synaptic release probability by gliotransmitters may occur on multiple time scales (De Pittà et al. 2015). On the one hand, it may last for tens of seconds up to a few minutes, thus affecting synaptic transmission and network computations only temporarily. In this context, theoretical investigations hint that synapses that display short-term depression can turn facilitating, and vice versa, by gliotransmission (De Pittà et al. 2011). At the same time, the filtering characteristic of the synapse for incoming APs also changes based on the history of astrocytic activation (De Pittà 2019). On the other hand, it is also possible for gliotransmission and its effects on synaptic transmission to last for tens of minutes: that is on time scales that could promote long-term plastic changes of the synapse. In this latter scenario, the change of synaptic weight w_{ij} of a synapse from neuron j to neuron i respectively firing at x_j , x_i , and in the presence of gliotransmitter release at rate γ , may be expressed by $\dot{w}_{ij} = F(w_{ij}; x_i, x_j, \gamma)$, where F is a generic function which we can expand about $x_i = x_j = \gamma = 0$, so that

$$\begin{aligned} \dot{w}_{ij} \approx & c_2^{\text{corr}} x_i x_j + c_2^{\text{pre}} x_i^2 + c_2^{\text{post}} x_j^2 \\ & + c_2^{\text{g-pre}} x_i \gamma + c_2^{\text{g-post}} x_j \gamma + c_2^{\text{glia}} \gamma^2 \\ & + c_1^{\text{pre}} x_i + c_1^{\text{post}} x_j + c_1^{\text{glia}} \gamma \\ & + c_0(w_{ij}) + O(x_i, x_j, \gamma) \end{aligned} \quad (10)$$

In the absence of gliotransmission ($c_2^{\text{g-pre}} = c_2^{\text{g-post}} = c_2^{\text{glia}} = c_1^{\text{glia}} = 0$), the above equation results in prototypical **“Hebbian Learning”** by $c_2^{\text{corr}} > 0$ (or anti-Hebbian learning for $c_2^{\text{corr}} < 0$) (Gerstner and Kistler 2002). This, however, may not be the case in the presence of gliotransmission, insofar as the requirements for associativity encompassed by Hebbian plasticity may not be sufficient to generate a change of synaptic weight. Correlation between pre- and postsynaptic activities reflected by c_2^{corr} in fact now sums with correlations between these activities and the effect of gliotransmission on pre-

($c_2^{\text{g-pre}}$) and postsynaptic receptors ($c_2^{\text{g-post}}$) (De Pittà and Brunel 2016), including additional effects on synaptic weight borne by gliotransmission alone which, for example, could mirror SICs which could be independent of postsynaptic activity (Wade et al. 2011).

Broadly speaking, how modulations of synaptic plasticity by glia could ultimately affect learning remains to be investigated, although few theoretical studies offer some enticing insights into the topic. Porto-Pazos and collaborators investigated performance of an astrocyte-inspired learning rule to train deep networks in data classification (Porto-Pazos et al. 2011; Alvarellos-González et al. 2012; Mesejo et al. 2015). They consider a feedforward network architecture where each neuron in the intermediate (hidden) layers associate with an astrocyte that modulates all the neuron’s outgoing connections. Each astrocyte is described by a quadruple (μ, κ, a, b) and requires μ stimulations by an associated synapse within κ consecutive time steps to get activated. Upon an astrocyte’s activation, the weights of all synapses associated with that astrocyte are increased by a factor a which could mimic either persistent increases of synaptic release by gliotransmission (Perea and Araque 2007; Navarrete et al. 2012) or LTP following enhanced postsynaptic NMDA receptor activation by astrocytically released D-serine (Henneberger et al. 2010). Conversely, if a neuron associated with an astrocyte remains inactive μ times within κ time steps, then the weights of its outgoing synapses are decreased by a factor b – a behavior that loosely reflects the termination of the aforementioned gliotransmitter-mediated effects, and accounts, in the long run, for pruning of inactive synapses (Hua and Smith 2004).

Several variants of the learning rule were tested, mostly dealing with different handling of astrocyte activations by consecutive neuronal firing exceeding μ ; yet, regardless of the details of the learning (training) procedure, the trained neuron-glia networks were able to outperform identical networks without astrocytes in all discrimination tasks taken into account (Porto-Pazos et al. 2011; Alvarellos-González et al. 2012). The training was, however, successful if potentiation

by astrocytes was less than depression by astrocyte inactivity, that is $a < b$ (Alvarellos-González et al. 2012; Mesejo et al. 2015). Because the change in synaptic weight mediated by an astrocyte at a synapse i at time t depends on the synapse's weight value at the previous update instant $t-1$, i.e., $\Delta w_i(t) = a \cdot w_i(t-1)$ for potentiation and $\Delta w_i(t) = b \cdot w_i(t-1)$ for depression, the $a < b$ condition assures that potentiation and depression do not cancel out at individual synapses, and that depression globally dominates, possibly preventing the network's runaway by excitation. On the other hand, the fact that $\Delta w_i(t)$ depends on $w_i(t-1)$, which in turn depends on $w_i(t-2)$ by $\Delta w_i(t-1)$ and so on, suggests that the relative contribution of potentiation over depression at any time at a given synapse depends on the history of synaptic updates which, in turn, reflects the history of the associated astrocyte's activation.

There is circumstantial evidence that astrocytes could modify the threshold for LTD versus LTP induction, such as in the supraoptic nucleus – where astrocytic coverage of synapse is reduced during lactation (Panatier et al. 2006). In these conditions, stimuli that are expected to induce LTP, elicit LTD instead, possibly for a reduced NMDA receptor activation by lower extracellular concentrations of astrocytic D-serine due to the increased extracellular space. Based on this experimental finding, and the observation that astrocytic D-serine could gate LTD or LTP induction (Zhang et al. 2008; Henneberger et al. 2010), Philips et al. (2017) devised a modified version of the BCM rule (Bienenstock et al. 1982; Gerstner and Kistler 2002) where the threshold rate of postsynaptic firing for induction of LTD versus LTP varies proportionally with astrocyte activation, and investigated how this rule affects development of orientation preference maps (OPMs) in a self-organizing network model of the primary visual cortex (V1) (Stevens et al. 2013). In their formulation, activation of an astrocyte is computed by the weighted sum of activities of all synapses within the astrocyte's anatomical domain of radius R , while the modified BCM rule only applies to excitatory connections, whereas inhibitory connections and excitatory afferents are trained by a classical Hebbian paradigm. This allows choosing the spatial range of

inhibitory connections to match short-distance lateral inhibitory connections found in V1 (Kisvárdy et al. 1997), while leaving the spatial range of lateral excitatory connections dependent on astrocytic radii.

This choice not only allows reproducing map orientation experimentally observed in V1 but also reveals that, upon reduction of astrocytic radius, periodicity of OPMs increases while width of individual hypercolumns decreases (Philips et al. 2017). Inasmuch as astrocyte size varies across species (Oberheim et al. 2009; López-Hidalgo et al. 2016), these results predict a causal link between astrocytic radius and different hypercolumn widths observed in different species (Kaschube et al. 2010). On the other hand, the model fails to explain why V1 in rodents displays a typical salt-and-pepper configuration (Ohki et al. 2005), inasmuch as it predicts the emergence of such configuration in the limit of $R \rightarrow 0$, that is in the absence of astrocytes, which is in apparent contradiction with experimental evidence (Schummers et al. 2008; Chen et al. 2012; Perea et al. 2014).

The type of sliding threshold introduced by Philips and co-workers is conceptually different from the one in the original BCM rule (Bienenstock et al. 1982). In this latter, the sliding threshold is a local quantity that depends on the history of the activation of individual postsynaptic neurons. Conversely, by exploiting the concept of “synaptic islands” – namely sets of synapses stimulating and being regulated by the same astrocyte (Halassa et al. 2007) – Philips and colleagues de facto consider a “global” threshold that modulates weight of many synapses in parallel, based on the integral of their activation by their associated astrocyte. In this way, it is as if each astrocyte in Philips et al.'s model supervised the signal inducing plastic changes (i.e., the “teaching signal”) throughout the whole synaptic territory defined by its anatomical radius.

The emerging view of Ca^{2+} compartmentation in astrocytes (Bazargani and Attwell 2016) suggests that, if Ca^{2+} is the mediator of gliotransmission (Sahlender et al. 2014), then its “globality” could be non-trivially defined, as it would likely depend, from time to time, on dynamics of Ca^{2+} microdomains, rather than be

solely defined by the astrocyte radius (Volterra et al. 2014). On the other hand, insofar as the criteria for globality are met, we shall note that the underpinning Ca^{2+} signal could be generated either by postsynaptically released endocannabinoids (Navarrete et al. 2014) or by different presynaptic pathways that are related to presynaptic neuronal firing. These presynaptic pathways could include the spillover of synaptically released neurotransmitters from the synaptic cleft (Araque et al. 2014), as well as other Ca^{2+} pathways linked with extracellular ion homeostasis (Fig. 1). Remarkably, if we consider this second option – namely that the global Ca^{2+} -dependent, gliotransmitter-mediated teaching signal carries information about the activity of presynaptic neurons – it is possible to envisage a biologically plausible learning rule to learn precise spike patterns and reproduce them precisely and robustly over trials. This argument was elegantly demonstrated by Brea et al. (2013) in recurrent networks where neurons were arbitrarily separated between visible versus hidden ones. In those networks, teaching to and accurate recall from visible neurons of an arbitrary spiking sequence is possible devising a learning rule that minimizes the Kullback-Leibler divergence of the spiking distribution produced by the network from the target distribution (i.e., the sequence to be learned). Such learning rule also discriminates between visible and hidden neurons and specifically modulates those synapses onto hidden neurons based on a threshold for LTD vs. LTP that is updated at each time step to account for the global activity of visible neurons. As the same authors argue that astrocytes could mediate this threshold, they also note that for this possibility to be realistic, astrocytes “need to know” which neurons are visible and which are hidden – a scenario that could be brought forth by a combination of the reciprocal arrangement between astrocytes and neuronal and vascular structures, and the chemical signals between them yet to be identified.

Glial Cytokine Signaling

There is emerging evidence that, apart from macroglia, microglia, too, could be involved in the genesis and function of neural circuits in the healthy brain (Kettenmann et al. 2013). This

possibility is further supported by the growing recognition that molecules like proinflammatory cytokines such as $\text{TNF}\alpha$, which are generally associated with the microglial immunocompetent response, but could also be released from astrocytes (Bezzi et al. 2001), may be found in healthy, non-inflamed brain tissue, possibly with a signaling role other than proinflammatory (Wu et al. 2015). Significantly, microglial could control extracellular $\text{TNF}\alpha$ in a bimodal fashion, first increasing it up to a peak concentration, and then recovering its constitutive extracellular concentration (Chao et al. 1995). Because at constitutive concentrations of <300 pM, $\text{TNF}\alpha$ seems necessary for glutamatergic gliotransmission, but above those concentrations, it could promote neurotoxicity (Santello and Volterra 2012), modeling of “Cytokine Networks, Microglia and Inflammation” may be used to identify critical macro- and microglial pathways underpinning this dual signaling role by $\text{TNF}\alpha$. In this context, variance-based global sensitivity analysis of a microglial cytokine signaling network identifies two further cytokines – IL-10 and $\text{TGF}\beta$ – as possible key regulators of microglial $\text{TNF}\alpha$. Both those molecules are promoted by $\text{TNF}\alpha$ while exerting negative feedback on it. However, because the kinetics of IL-10-mediated feedback is faster than that by $\text{TGF}\beta$, they can end up exerting opposing effects on extracellular $\text{TNF}\alpha$, depending on temporal differences in their expression: reduction of $\text{TNF}\alpha$ peak concentration by IL-10 may indeed be counteracted by the ensuing reduction of $\text{TGF}\beta$ production with the potential to turn the traditionally anti-inflammatory action of these cytokines, proinflammatory instead (Anderson et al. 2015).

The study of $\text{TNF}\alpha$ signaling, possibly of (micro)glial origin, is also linked with homeostatic mechanisms of synaptic plasticity (Steinmetz and Turrigiano 2010). A case study is the mechanism of ocular dominance plasticity (ODP) whereby monocular deprivation (MD), during a critical period of development, causes a rearrangement of neuronal firing properties in the binocular visual cortex. In this fashion, cells that are initially biased to respond to inputs from the closed eye end up responding more strongly to inputs from the open eye (Wiesel 1982). As

revealed by experiments in the visual cortex of juvenile mice, MD-triggered ODP results from two separable plastic processes: (i) a rapid, Hebbian-like LTD, that is responsible for weakening the closed eye's response within the first 3 days of MD and (ii) a slow homeostatic response where TNF α – possibly of glial origin – scales up excitatory synapses and strengthens the open eye's response approximately by the third day of MD (Kaneko et al. 2008). Because of the large separation between time scales of Hebbian versus homeostatic plasticity, conventional models of synaptic plasticity where Hebbian and homeostatic plasticity are assumed to compete to set synaptic strength cannot account for MD-induced ODP. In those models, in fact, a small perturbation of synaptic strength away from equilibrium is promptly amplified by the fast positive feedback of Hebbian plasticity, and this amplification can hardly be prevented by the slow homeostatic feedback, making the network prone to instability (Toyoizumi et al. 2014; Zenke et al. 2017). To avoid this scenario, an adequate description of MD-induced ODP should leverage instead on the consideration that observed Hebbian LTD and glial homeostatic scaling are independent of each other during MD (Kaneko et al. 2008) so that they both must separately reach their own stable state for the network to be stable. This could, in principle, be accounted for by the fact that plastic changes induced both by Hebbian learning and by homeostatic scaling can saturate to minimal and maximal values, making these two plasticity mechanisms inherently stable (Beattie et al. 2002; O'Connor et al. 2005). However, in practice, at least two further conditions must be met to be able to reproduce ODP robustly (Toyoizumi et al. 2014). First, homeostatic plasticity must also scale minimum and maximum values of synaptic strength attained by mere Hebbian learning. Second, homeostatic scaling must depend on instantaneous neuronal activity, like postsynaptic depolarization, since this latter correlates with extracellular glutamate levels, which, in turn, regulate the glial release of TNF α (Bezzi et al. 2001; Stellwagen and Malenka 2006). Based on these arguments then, it is possible to devise a working model of

MD-induced plasticity where synaptic strength w can be recast as the product of two factors: a synapse-nonspecific factor H , applicable to the whole postsynaptic cell and controlled by slow glial TNF α -mediated homeostatic scaling, and a synapse-specific factor ρ regulated by fast Hebbian plasticity, i.e., $w = H \cdot \rho$ (Toyoizumi et al. 2014). This description of synaptic strength then accounts for the intriguing possibility that slow glial TNF α signaling in the visual cortex could intrinsically balance with fast Hebbian plasticity by instantaneously rescaling the range of synaptic strength values attained by Hebbian learning. The multiplicative scaling envisaged by the expression for w is critical for glial homeostasis to maintain the relative strength between different synapses. Moreover, because it also affects minimal and maximal synaptic weights, it can thereby bring the network's activity level toward equilibrium without disturbing the intrinsic stability of the Hebbian dynamics and without being overwritten by this latter. In parallel, the presumed instantaneous dependence of H on (post)synaptic activity guarantees network stability making glial homeostasis able to readily follow perturbations of the network's activity caused by fast Hebbian learning (Toyoizumi et al. 2014).

Temporal and Spatial Scales of Neuron-Glial Interactions

Morphology and Structural Plasticity

The large heterogeneity of glial cells, even within individual types such as oligodendrocytes, microglia, and astrocytes, makes the notion of average cell anatomy of little significance. The number of axons myelinated by single oligodendrocytes, for example, considerably changes with axon caliber, and so does the degree of myelination in terms of internodal lengths, ultimately dictating different conduction speeds. Oligodendrocytes are generally classified into four types, depending on the caliber of the axons they myelinate, with the possibility for intermediate types to exist too. Accordingly, types I/II are found in association with small (<4 μm) axons, whereas types III/IV myelinate

larger axons. The morphological values provided in Table 1 are from Butt (2013).

More complicated is the description of microglia since, in the healthy brain, these cells display a ramified morphology whose processes continuously extend and retract at rates of 0.4–3.8 $\mu\text{m}/\text{min}$ (Nimmerjahn et al. 2005). The classical study by Lawson et al. (1990) arguably still provides the most comprehensive characterization of microglia anatomy and distribution in the brain up-to-date. Accordingly, microglia were shown to be present in large numbers in all major divisions of the brain but not to be uniformly distributed. There is, in fact, a more than five-fold variation in the density of microglial processes between different regions, with higher density in the hippocampus, average one in the cortex and hypothalamus, and lower one in the cerebellum. Overall, microglia surface density ranges between ~ 50 and 140 cells/ mm^2 , with individual cells displaying a large variability in surface area, from <200 μm^2 in the cortex to >500 μm^2 in the hippocampal formation, which likely associates with variegated morphological complexity, as reflected by a perimeter-to-convex perimeter ratio of 5 for cortical microglia but >8 for microglia in the hippocampus. Volumetric data on microglia is not yet available.

Protoplasmic astrocytes represent the main astrocyte type in the gray matter and appear to be among the most structurally intricate cells of the brain (Reichenbach and Wolburg 2013). They display a highly branched morphology with some degree of polarization that is probably region-specific (Chao et al. 2002). At least one of the cell branches (or “processes”) is bearing one or several perivascular endfeet such that the surfaces of the blood vessels in the CNS are virtually completely ensheathed by astrocytic endfoot plates (Mathiisen et al. 2010). Astrocyte volume in rodents has been reported to range from $14,700$ – $22,906$ μm^3 in the cortex to $65,900$ – $85,300$ μm^3 in the hippocampus (Bushong et al. 2002; Ogata and Kosaka 2002; Chvátal et al. 2007; Halassa et al. 2007). These figures, however, are not indicative of the morphological complexity of these cells, as mirrored instead by a large surface-area-to-volume ratio in the range of 18.9 – 33.0 μm^{-1} (Hama et al. 2004).

Single anatomical domains of cortical astrocytes were reported to include from 4 to 8 neuronal somata (Halassa et al. 2007). A direct measure of the number of synapses within an astrocytic domain instead is not available but can be estimated from synaptic densities. With this regard considering an average of 0.89 synapses/ μm^3 in the cortex (Kasthuri et al. 2015) and 2.13 synapses/ μm^3 in the hippocampus (Kirov et al. 1999), we get figures for the number of synapses within the above astrocytic volumes that equal to $\sim 13,000$ – $20,400$ synapses/astrocyte in the cortex and $\sim 140,000$ – $182,000$ synapses/astrocyte in the hippocampus.

It is not clear to what extent the number of synapses ensheathed by astrocytes could change during activity by structural plasticity of perisynaptic astrocytic processes (Haber et al. 2006), and cell swelling (Florence et al. 2012), but, likely, the functional interactions between astrocytic and synaptic elements do so. Typical rate values for changes of cell morphology and ECS shrinkage ensuing from astrocytic swelling can then be estimated by experimental observations that directly link these changes with (putative) functionally relevant levels of neuronal activity. With this regard, perisynaptic astrocytic processes undergo multiple retractions and protrusions of >5 μm length in correlation with neuronal activation (Haber et al. 2006), and LTP induction correlates with an average remodelling rate of <40 nm/s in hippocampal astrocytic processes (Perez-Alvarez et al. 2014). Putative physiological HCO_3^- increases in the ECS trigger astrocytic swelling, which can be quantified in terms of percentage variation of the cell’s surface area to baseline HCO_3^- concentrations. This swelling can be well described by a monoexponential curve of the type $\Delta_{\text{max}}(1 - \exp(-rt))$ with $r = 0.08$ s, $\Delta_{\text{max}} \approx 20\%$, resulting in an initial linear rate of surface area increase of ~ 1.5 $\Delta\%/s$ ($\Delta\%/s$: percentage variation in the unit time) (Florence et al. 2012). Alternatively, ECS shrinkage, possibly related to astrocyte swelling, appears to increase linearly with duration of stimulation by rates in between ~ 0.3 and 0.7 $\Delta\%/s$, and to recover original volumes upon cessation of stimulation with decay times >10 s (Larsen et al. 2014).

Neuron-Glial Interactions, Table 1 Some relevant spatial and temporal scales of glial signaling in the murine brain

Description	Range	Units
<i>Morphological features</i>		
Oligodendrocytes (type I/II)		
Associated fiber diameter	<4	μm
Number of myelinated axons per cell	10–50	–
Internodal length	~10–350	μm
Associated axonal conduction speed	<20	μm/s
Oligodendrocytes (type III/IV)		
Associated fiber diameter	>4	μm
Number of myelinated axons per cell	1–10	–
Internodal length	~400–1000	μm
Associated axonal conduction speed	80–120	μm/s
Microglia		
Surface density	50–140	cells/mm ²
Surface area	>200–500	μm ²
Perimeter-to-convex perimeter ratio	>5–8	–
Astrocytes (protoplasmic type)		
Cell volume	14,700–85,300	μm ³
Surface area-to-volume ratio	18.9–33	μm ^{–1}
Neurons per cell	4–8	–
Synapses per cell	13,000–182,000	–
<i>Structural plasticity</i>		
Process motility		
Astrocytes	<40	nm/s
Microglia	0.4–3.6	μm/min
Astrocytic swelling		
HCO ₃ [–] -mediated percentage cell surface area increase	<1.5	Δ%/s
Activity-dependent associated ECS shrinkage	<0.3–0.7	Δ%/s
ECS volume recovery time	>10	s
<i>Non-astrocytic Ca²⁺ signaling</i>		
Oligodendrocytes (soma)		
Rise time	5.2–7.7	s
Decay time	5.5–7.8	s
FWHM	11.6–16.8	s
Microglia (soma)		
Rise time	0.5–1.1	s
Decay time	4.9–5.1	s
FWHM	2.6–5.2	s
<i>Astrocytic Ca²⁺ signaling</i>		
Soma		
Frequency	5.8–9.2	mHz
Rise time	2–20	s
Decay time	3–25	s
FWHM	5–160	s
Processes		
Frequency	6–8	mHz
Rise time	<0.2–5	s
Decay time	6–10	s
FWHM	0.35–3	s

(continued)

Neuron-Glial Interactions, Table 1 (continued)

Description	Range	Units
Endfeet		
Frequency	29–40	mHz
Rise time	3–18	s
Decay time	2–30	s
FWHM	0.75–12	s
Onset delay (from stimulation)	<0.3–3	s
Microdomain volume		
Soma	~890–10,000	μm^3
Processes	~37–85	μm^3
Propagation		
Intracellular speed	~8–24	$\mu\text{m/s}$
Intercellular speed	~8–80	$\mu\text{m/s}$
<i>GGC and ANLS</i>		
Glutamate uptake		
Rise time	0.9–6	ms
Decay time	4.6–5.4	ms
GABA uptake rate		
Rise time	410–544	ms
Decay time	0.9–4.3	s
Glutamine synthesis	0.13–0.21	$\mu\text{mol/min}$
Lactate metabolism (rise/decay time)	4.1–5.2	s
<i>Glilotransmission</i>		
Presynaptic pathway (glutamate, release-increasing)		
Rise time	>0.05–28.3	s
Decay time	5.9–95.7	s
Presynaptic pathway (purines, release-decreasing)		
Rise time	1.6–8.2	s
Decay time	8.2–12	s
Postsynaptic pathway		
LTP rate (D-serine)	0.3–4.0	$\Delta\%/min$
TNF α -mediated AMPA receptor variation	± 5 –12	$\Delta\%/min$
TNF α -mediated GABA $_A$ receptor variation	–0.3–0.7	$\Delta\%/min$
<i>Ion homeostasis</i>		
K $^+$ buffering		
Rise time	0.8–5.1	s
Decay time	3.9–18.6	s
Propagation	>30	$\mu\text{m/s}$
Na $^+$ spatial buffering	>2–80	$\mu\text{m/s}$
<i>Vascular coupling</i>		
Vasodilation		
Max % variation upon astrocytic Ca $^{2+}$ stimulation	5–8	$\Delta\%$
Percentage vessel diameter change rate	>0.05–0.37	$\Delta\%/min$
Vasoconstriction		
Max % variation upon astrocytic Ca $^{2+}$ stimulation	9–27.5	$\Delta\%$
Percentage vessel diameter change rate	1.6–1.7	$\Delta\%/s$
Onset delay from astrocyte activation	<1–3	s

Calcium Signaling

Study of Ca^{2+} signaling in microglia and oligodendrocytes is still in its infancy and the only estimates of rise (τ_r), decay times (τ_d), and full width at half maximum (FWHM) of this signaling pathway may be derived from purinergically evoked Ca^{2+} elevations in microglia in vivo (Brawek et al. 2017; Brawek and Garaschuk 2017) and oligodendrocyte in situ (James and Butt 2001). Time constant are estimated by fitting experimental Ca^{2+} traces ($c(t)$) by a difference of two exponential, i.e., $c(t) = C (\exp(-t/\tau_d) - \exp(-t/\tau_r))$ where C is a normalization factor equal to $C = (T^{\tau_d} - T^{\tau_r})^{-1}$ with $T = \tau_r/\tau_d$ and $\tau_x = \tau_r\tau_d/(\tau_d - \tau_r)$. Accordingly, for oligodendrocytes (based on $n = 20$ Ca^{2+} traces): $\tau_r = 6.5 \pm 1.2$ s, $\tau_d = 6.7 \pm 1.1$ s, and FWHM = 14.2 ± 2.6 s; and for microglia ($n = 6$): $\tau_r = 0.8 \pm 0.3$ s, $\tau_d = 5.0 \pm 0.1$ s, and FWHM = 3.9 ± 1.3 s.

The vast majority of observations on glial Ca^{2+} signaling has been made so far on astrocytes, although several aspects of this signaling remain to be investigated and cannot be challenged by present techniques (Rusakov 2015). For example, it is not yet possible to resolve Ca^{2+} signals in fine perisynaptic astrocytic processes (e.g., lamellae or filopodia), although we are now in the conditions of resolving Ca^{2+} dynamics in the three-dimensional space (Bindocci et al. 2017). Generally speaking, when considering astrocytic Ca^{2+} signals in vivo, different factors beyond development and technical approaches must be taken into account, such as whether these signals were recorded in awake or asleep/anesthetized animals, what brain area they occurred in, if they are spontaneous or evoked by stimulation, and in this latter case, what stimulus protocol was adopted (Rusakov 2015). In what follows, we only consider estimates for protoplasmic astrocytes, which constitute the main astrocyte type of the rodent's gray matter. The reader should keep in mind that Ca^{2+} dynamics in other astrocyte types as well as in Müller cells and Bergmann glia could be different (Matyash and Kettenmann 2010).

In astrocytes, spontaneous somatic/whole cell Ca^{2+} signals are rare ($\nu \approx 5.8\text{--}9.2$ mHz) and characterized by a rise time in the range of $\tau_r \approx 2\text{--}20$ s,

a decay time $\tau_d \approx 3\text{--}25$ s, and a full width at half maximum FWHM $\approx 5\text{--}160$ s (Hirase et al. 2004; Nimmerjahn et al. 2004; Wang et al. 2006; Bindocci et al. 2017). Recent estimates of these quantities in microdomains of astrocytic processes and endfeet provide: $\nu \approx 6\text{--}8$ mHz, $\tau_r < 0.7\text{--}5$ s, $\tau_d < 6\text{--}10$ s, FWHM $\approx 0.35\text{--}3$ s in processes, and $\nu \approx 29\text{--}40$ mHz, $\tau_r < 3\text{--}18$ s, $\tau_d < 2\text{--}30$ s, FWHM $\approx 0.75\text{--}12$ s at endfeet (Bindocci et al. 2017). The onset delay of these events can be remarkably short and follow neuronal stimulation within $<0.3\text{--}3$ s (Winship et al. 2007; Bindocci et al. 2017; Stobart et al. 2018). Significantly, there appears to exist a clear distinction in distribution of values of ν , τ_r , and τ_d with respect to Ca^{2+} events whose FWHM is below versus above ~ 1.5 s (Bindocci et al. 2017). Furthermore, size of Ca^{2+} microdomains in processes appears slightly larger during stimulation with respect to resting state, i.e., $60.7 \pm 24.3 \mu\text{m}^3$ versus $40.50 \pm 3.11 \mu\text{m}^3$, whereas a large dynamical richness of Ca^{2+} events is reported at the somatic level, with average signaling volumes of the order of $4470 \pm 1051 \mu\text{m}^3$, with largest events being in the order of $6375 \pm 1106 \mu\text{m}^3$ (estimated range of $\sim 890\text{--}10,000 \mu\text{m}^3$) (Bindocci et al. 2017). Intracellular Ca^{2+} propagation may be estimated in the range of $\sim 16 \pm 8 \mu\text{m/s}$ (Di Castro et al. 2011, Supplementary Fig. 5), whereas speed of intercellular Ca^{2+} waves, measured mostly in brain slices so far, is in the range of $\sim 8\text{--}20 \mu\text{m/s}$ (Scemes and Giaume 2006; Oberheim et al. 2009), although a recent study in vivo reported on large Ca^{2+} waves that could recruit >80 astrocytes, and propagate as fast as $61 \pm 22 \mu\text{m/s}$ (Kuga et al. 2011).

Glutamate-Glutamine Cycle and Astrocyte-to-Neuron Lactate Shuttle

Both GGC and ANLS rely on glutamate (and GABA) uptake by astrocytic transporters. The transporter currents for these two neurotransmitters recorded in hippocampal astrocytes display a marked time scale separation. In the adult mice, the 20–80% time rise of astrocytic glutamate uptake was estimated in the range of 0.92–1.65 ms (Diamond 2005) although some

investigators suggest that a longer 10–90% rise time, up to 5.98 ± 0.38 ms, could also be reached (Kinney and Spain 2002). Decay times are instead reported in the range of 4.64–5.43 ms. GABA uptake is substantially slower with 10–90% rise and decay time constants comprised between >410.5–543.83 ms and >0.93–4.34 s, respectively (Kinney and Spain 2002). A further limiting factor of GGC and ANLS is substrate availability, for which little is known in vivo so far. Nuclear magnetic resonance data in anesthetized rats suggest a rate of glutamine synthesis by astrocytes between ~ 0.13 and $0.21 \mu\text{mol}/\text{min} \cdot \text{g}$, which is nearly half of the estimated consumption rate of glutamate by Krebs cycle, thus hinting glutamine synthesis as a major metabolic pathway in the rat cortex (Sibson et al. 1997; Rothman et al. 2003). For lactate production by individual astrocytes, astrocytic intracellular NADPH signaling in response to synaptically activated metabotropic glutamate receptors (mGluRs) can be adopted as the readout of different scenarios of neuronal activity and brain states in conditions of simulated hyperemia (high pO_2) or vasoconstriction (low pO_2) (Gordon et al. 2008). This is because the enzyme that is responsible of lactate synthesis – i.e., lactate hydrogenase – is NADPH-dependent (Fig. 1, *purple pathway*) so that increases and decreases of NADPH following mGluR-mediated astrocytic activation can directly be linked to intracellular lactate metabolism by astrocytes, resulting in estimates for rise and decay time constants for this latter in between 4.1 and 5.2 s, with lower values associated with high pO_2 and vasoconstriction (Gordon et al. 2008).

Gliotransmission

Estimates of time scales of modulation by gliotransmitters should be based on experimental data (mostly in situ) that provide information on the time evolution of the effect of gliotransmission on synaptic transmission. Table 1 includes such estimates for short- and long-term effects of release-increasing glutamatergic gliotransmission, and short-term, release-decreasing purinergic gliotransmission (Perea and Araque 2007; Covelo and Araque 2018). A biexponential function (section “Calcium Signaling”) can be used to fit

time series data of synaptic release probability ($p(t)$) following astrocytic Ca^{2+} activation (set at $t = 0$), thereby obtaining: for glutamatergic gliotransmission $\tau_r > 0.05$ – 0.2 s, $\tau_d = 5.9$ – 6.7 s ($n = 2$, short-term); $\tau_r = 6.2$ – 28.3 s, $\tau_d = 18.7$ – 95.7 s ($n = 3$, long-term); for purinergic gliotransmission ($n = 2$): $\tau_r = 1.6$ – 8.2 s, $\tau_d = 8.2$ – 12.0 s. It is also possible to estimate the rate of D-serine-dependent synaptic potentiation in terms of percentage variation of synaptic strength in the unit time, under the assumption of a linear increase of synaptic strength in the presence of activity-dependent D-serine release from astrocytes. The range of values for this postsynaptic pathway of gliotransmission provided in Table 1 was estimated from Yang et al. (2003) and Takata et al. (2011).

Concerning regulation of AMPA and GABA_A receptors by glial TNF α (Stellwagen and Malenka 2006), the average rate of change for expression of postsynaptic AMPA and GABA_A receptors by glial TNF α (Stellwagen and Malenka 2006) may be derived from the ratio between the total percentage change or receptor expression with respect to control ($\Delta\%$) over the duration of TNF α stimulus (T_α). In this fashion, for hippocampal receptors: $157\% \pm 15\%$ increase of AMPA receptors, and $12\% \pm 4\%$ decrease of GABA_A receptors were reported for TNF α applications of $T_\alpha = 15$ – 25 min (Stellwagen et al. 2005), whereas a decrease of 25–30% of GABA_A receptors was measured for $T_\alpha = 45$ min (Pribiag and Stellwagen 2013). These data translate into rate values of ~ 5 – $12 \Delta\%/\text{min}$ and ~ -0.3 – $0.7 \Delta\%/\text{min}$, respectively, for AMPA and GABA_A changes. One should, however, keep in mind that the effect of TNF α is region and/or cell-specific, insofar as the AMPA-to-NMDA ratio was shown to increase from 1.75 to 3 in hippocampal pyramidal cells in the presence of TNF α ($T_\alpha = 1$ – 2 h), but to decrease from 3.7 to 2.5 at medium spiny neurons in the striatum (Lewitus et al. 2014).

Ion Homeostasis

Extracellular ion homeostasis depends on the brain region and evolves with ongoing neuronal activity. At the rat’s optic nerve, glia K^+ buffering

displays a typical bi-exponential behavior, with a rise time that may slightly increase from ~ 0.83 s to ~ 1.6 s as a 10 Hz stimulus is delivered either for 1 s or 10 s (Ransom et al. 2000). Buffering time by re-equilibration of extracellular K^+ concentration, mostly by inward-rectifying K^+ channels in combination with NKPs, is typically large, being comprised between 3.9 ± 1 s and 18 ± 0.6 s (Ransom et al. 2000; D'Ambrosio et al. 2002; Chever et al. 2010). Significantly, this buffering time may considerably shorten in the presence of glial Ca^{2+} signaling, and thereby modulations of glial NKPs, with both rise and decay time of extracellular K^+ converging to ~ 0.9 – 5.0 s (Wang et al. 2012a, b). There is little information on the spatial extent of glia-mediated K^+ buffering in vivo, although intracellular recordings in glia pairs in the suprasylvian gyrus suggest that it is probably fast, with propagation speeds >30 $\mu\text{m}/\text{second}$ (Amzica et al. 2002). Intriguingly, intracellular Na^+ propagation in hippocampal astrocytes (although demonstrated so far in situ) could be at least twofold faster but decay to 2 – 10 $\mu\text{m}/\text{s}$ for intracellular glial sites >60 μm far from the stimulus locus (Langer et al. 2012).

Regulation of the Blood Flow

Ca^{2+} -dependent regulation of blood flow by astrocytes is dependent on brain state, possibly with vasoconstriction observed in the presence of hyperemia, and vasodilation in association with hypoemia (Gordon et al. 2008). The onset of astrocyte-mediated dilations or constrictions in different brain areas, generally occurs within <1 – 3 s from the start of astrocytic Ca^{2+} signaling (Zonta et al. 2003; Mulligan and MacVicar 2004; Otsu et al. 2015). On the other hand, astrocytes seem to promote vasoconstriction to a larger magnitude then vasodilation, since reported percentage decreases of blood vessel diameters mediated by astrocytes could be $>20\%$, whereas observed increases are generally $<10\%$ (Zonta et al. 2003; Mulligan and MacVicar 2004; Gordon et al. 2008). This is mirrored by linear rates of percentage vessel diameter variation that range between 1.6 and 1.7 $\Delta\%/s$ for vasoconstriction (Mulligan and MacVicar 2004) but only between >0.05 and 0.3 $\Delta\%/s$ for vasodilation (Zonta et al. 2003).

Significantly, these figures depend on the number of astrocytic endfeet simultaneously activated on the same blood vessel, since, for example, a single endfoot could trigger a $9.1 \pm 0.7\%$ vasoconstriction, but multiple endfeet could account for a threefold larger reduction of vessel diameter (Mulligan and MacVicar 2004).

Conclusion

Modeling of neuron-glia interactions is an emerging field of computational neuroscience. The ubiquity of these interactions and the possibility that they may occur within the time and spatial scales that are usually ascribed to neuronal and synaptic function calls for a revision of current neuron-based modeling paradigms to include potentially relevant effects mediated by glial cells. The modeling arguments discussed in this chapter go in such direction, further hinting a fundamental design of neuronal circuits where their structure and function are possibly intertwined with that of glia, thereby challenging the traditional Neuron Paradigm of the brain, in favor of an extended, more realistic neuron-glia one.

[Network disorders](#)

Definition

Brain disorders often coincide with changes in the white and gray matter organization. When we view the gray matter brain regions as nodes of a network, the white matter fiber tracts become the edges. Changes in the nodes or edges of a network can be a sign of brain network disorders. Edge changes might affect spatial features such as the distance between connected nodes or the three-dimensional trajectory of fibers and topological features such as the fiber strength given by the extent of myelination or the thickness of fiber tracts. Such local changes can affect the global modular hierarchical, small-world, or rich-club organization.

Detailed Description

Types of Brain Networks

For brain networks, nodes could be neurons or cortical areas and edges could be axons or fiber tracts. Thus, edges could refer to the *structural connectivity* of a neural network. Alternatively, edges could signify correlations between the activity patterns of nodes forming *functional connectivity*. Finally, a directed edge between two nodes could exist if activity in one node modulates activity in the other node forming *effective connectivity* (Sporns et al. 2004; Kaiser 2011).

Edges could be binary, in that only existing and nonexistent edges are distinguished. In this case, changes could only consist of the formation or removal of edges. Such changes would affect the number of edges of a node or, in other words, the degree of a node. Alternatively, edges could be weighted. For functional networks, weights could signify the correlation between the time series of activity in two nodes in the range of -1 to 1 . For structural networks, weights could indicate the strength of a connection given by the fiber diameter and volume or by the number of streamlines or the fractional anisotropy (FA) in diffusion imaging.

It is important to keep in mind that edge weights could either use metric or ordinal scales leading to different analysis approaches. For example, while the number of streamlines is a metric scale, the connection strength in the CoCoMac database of macaque tract tracing data is on the ordinal scale (1:weak, 2:medium, 3:strong). Unlike a metric scale, a connection in the macaque brain labeled with a strength of 2 is not twice as large as a strength of 1.

Network Topologies

Brain networks can show features of several classes of archetype networks (Fig. 1). For example, an individual brain network might have properties of small-world, modular, and hierarchical networks. In addition, network topology might differ at different levels of organization with random or regular axonal connectivity for small neuronal populations and modular connectivity for cortico-cortical fiber tracts (Kaiser and Varier 2011).

Random Networks

Whereas many networks are generated by a random process, the term random network normally refers to the type of Erdős-Rényi random networks (Erdős and Rényi 1960). Random networks are generated by establishing each potential connection between nodes with a probability p . This probability, for a sufficiently large network, is

Neuropathologies and Networks, Fig. 1 *Types of networks.* (a) Erdős-Rényi random network. (b) Scale-free network with dark edges (*top*) indicating highly connected nodes or hubs. (c) Regular or lattice network with high connectivity between neighbors. (d) Small-world network

with blue edges (*top*) representing shortcuts of the network. (e) Modular network with two modules. (f) Hierarchical network with two modules consisting of two sub-modules each. Thus, there are two hierarchical levels of organization. (Adapted from Kaiser 2011)

then equivalent to the edge density of the network, i.e., the connection density. The process of establishing connections resembles flipping a coin where an edge is established with probability p and not established with probability $q = 1 - p$. Therefore, the distribution of node degrees follows a binomial probability distribution.

Scale-Free Networks

Scale-free networks are characterized by their specific distribution of node degrees. The degree distribution follows a power law where the probability that a node with degree k exists or the frequency of occurrences for real-world networks is given by $P(K) \sim k^{-\gamma}$. For functional connectivity between voxels in human MRI, γ was found to be 2.0 (Eguiluz et al. 2005) whereas γ was 1.3 for functional connectivity of neurons in the hippocampus determined through calcium imaging (Bonifazi et al. 2009).

Small-World Networks

Many networks exhibit properties of small-world networks (Watts and Strogatz 1998). The term small world refers to experiments in social networks by Stanley Milgram where a person could reach any other person through a relatively short chain of acquaintances, the “six degrees of separation” (Milgram 1967). Small-world networks are in the middle between regular networks where neighbors are well connected and no long-range connections exist and random networks where long-range connections exist, but there are no more connections between neighbors of a node than between any two nodes in the network (Watts and Strogatz 1998).

Modular and Hierarchical Networks

Clusters or modules are parts of a network with many connections (high edge density) within such a part and few connections (low edge density) to the remaining nodes of the network. There are many different algorithms to detect clusters of a network (Hilgetag et al. 2000b; Girvan and Newman 2002; Palla et al. 2005). Hierarchical networks follow a modular organization at different levels: modules at a gross resolution might consist of several sub-modules at a more fine-grained resolution. For example, network analysis approaches can identify a network module that represents the macaque visual system, but further analysis of this module can identify the dorsal and ventral stream as sub-modules (Hilgetag et al. 2000a).

Spatial Network Features

Brain networks also have spatial properties in that each node and edge has a three-dimensional location and extension may it be volume for nodes or diameter and trajectory for edges. The actual wiring between nodes can also inform us about functional constraints. For example, long-distance connections are costly in that their establishment and their maintenance uses energy (Laughlin et al. 1998). On the other hand, long-distance connections can form shortcuts that lead to faster information integration and, consequently, accelerated reaction time (Kaiser and Hilgetag 2006).

Between groups, it can be tested whether the distribution of connection lengths is changing (Kaiser et al. 2009). Looking at the length

distribution is especially useful to identify changes in the frequency of long-distance connections (Kaiser 2011). Here, distance could be either the Euclidean distance between the centers of brain regions/neuron locations or the actual length of the trajectory that a fiber tract or axon is following through three-dimensional space. As connections tend to grow in a straight line and fiber tracts are mostly not strongly curved (Hilgetag and Barbas 2006), the Euclidean distance can often be a useful approximation of connection length (Kaiser 2011).

Network Changes for Neuropathologies

Changes for network disorders can involve any single or combination of topological or spatial features discussed above. However, here we will focus on three changes that are well studied: changes in hub organization, changes in modular architecture, and changes in long-distance connectivity. In this fast-moving field, we can only show a small selection of studies and brain diseases.

Starting with neurodevelopmental disorders, schizophrenia is characterized by changes in the connection length distribution (Alexander-Bloch et al. 2013), in small-world and modular organization (Micheloyannis et al. 2006; Bassett et al. 2008; Liu et al. 2008), and in other functional connectivity measures (Woodward et al. 2011).

For epilepsy, the modular organization of functional connectivity (Chavez et al. 2010; Vaessen et al. 2013), the link between structural and functional connectivity (Zhang et al. 2011), and various other neuroimaging biomarkers (Mishra et al. 2011) are affected.

For ageing-related diseases, hub functional connectivity changes were shown for late-life depression (Bohr et al. 2013), and various network changes were shown for dementia and Alzheimer's disease (de Haan et al. 2009; Xie and He 2011; Raj et al. 2012).

These changes in structural and functional connectivity are presumed to have direct implications on the dynamics and function of neural systems. Changes in the modular architecture with stronger

links between modules can facilitate the spreading of activity and presumably increase the likelihood of epileptic seizures (Kaiser et al. 2007; Kaiser and Hilgetag 2010). Highly connected nodes or hubs can be crucial for the integration of information either within modules (provincial hubs) or between modules (connector hubs) (Sporns et al. 2007; Zamora-Lopez et al. 2010).

Summary

Conceptually, any deviation of the network organization in healthy subjects can be argued to be linked to brain pathologies. For example, both cognitive deficits in patients and the intelligence quotient in healthy subjects can be linked to brain network properties (Stam et al. 2007; van den Heuvel et al. 2009). Stam and colleagues proposed that changes in small-world organization, moving the network either closer to a random network or closer to a regular network, are a signpost of diseases (Reijneveld et al. 2007). Kaiser, Hilgetag, Bullmore, and others argued that changes in the (hierarchical) modular organization are linked to diseases (Kaiser et al. 2007; Meunier et al. 2010). Sporns and colleagues argue that links to the hub organization, the rich-club network, are linked to cognitive deficits in patients (van den Heuvel et al. 2012; Collin et al. 2013). Finally, changes in the frequency of long-distance connections might be linked to the integration of information in neural systems (Kaiser and Hilgetag 2006).

Neuropercolation and Neural Population Models

Robert Kozma

Department of Mathematical Sciences, University of Memphis, Memphis, TN, USA

Definition

Neuropercolation is a family of probabilistic models based on the mathematical theory of probabilistic cellular automata on lattices and random graphs. Neuropercolation is motivated by the structural and dynamical properties of large-scale neural populations. Neuropercolation extends the concept of phase transitions to interactive neural populations exhibiting frequent sudden transitions in their spatiotemporal dynamics. Neuropercolation develops equations for the probability distributions of macroscopic state variables by generalizing percolation theory as an alternative to models based on differential equations.

Detailed Description

Mathematical Description of Neuropercolation

Neuropercolation uses the tools of random graphs and percolation theory developed over the past 50 years to establish a rigorous model of brain

networks with complex dynamics (Erdos and Renyi 1960; Bollobás 1985; Bollobas and Riordan 2006). Neuropercolation is a natural domain for modeling collective properties of brain networks, especially near critical states, when the behavior of the system changes abruptly with the variation of some parameters. Consider a graph on a d dimensional lattice; in cortical models usually two-dimensional lattices are studied ($d = 2$). In the original bootstrap percolation model, the sites are active or inactive (1 or 0), and their activation evolves in time step-by-step. At first, each site is activated with probability (p), and then they are updated according to a given rule. In the original bootstrap percolation model, the update rule is deterministic: an active site always remains active, and an inactive site becomes active if at least k of its neighbors is active at the given time (Aizeman and Lebowitz 1988).

If the iterations ultimately lead to a configuration when all sites become active, it is said that there is “*percolation*” in the lattice. A main question of bootstrap percolation concerns the presence of percolation as the function of lattice dimension d , initial probability p , and neighborhood parameter k . A fundamental result of percolation theory states (Bollobas and Riordan 2006) that on infinite lattices, there exists a critical probability $p_c = f(d, p, k)$ with the property, that for

$$p > p_c \text{ there is percolation}$$

$$p \leq p_c \text{ there is no percolation}$$

The above critical property is valid for arbitrary initial configurations, with the exception of some special configurations of zero measure in the configuration space. Next, the case of majority percolation is considered, when k is the majority of the nodes in the neighborhood. For example, in the 2-dimensional square lattice with direct neighbors, the majority is $k = 3$, as the neighborhood consists of five nodes (the four neighbors and the node itself). In neuropercolation, the bootstrap property is relaxed, i.e., a site is allowed to turn from active to inactive. Related mathematical concepts are described by cellular automata, such as Conway’s Game of Life, Chua’s cellular neural

networks, Ising spin lattices, and Hopfield nets (Berlekamp et al. 1982; Hopfield 1982; Chua 1998; Newman et al. 2002).

Neuropercolation incorporates the following major generalizations of percolation based on the features of the neuropil, the filamentous neural tissue in the cortex:

1. *Noisy interaction*: The dynamics of the interacting neural populations is inherently nondeterministic due to dendritic noise and other random effects in the nervous tissue and external noise acting on the population. Neuropercolation includes a small random component ($\varepsilon > 0$) in the majority voting rules. In the simplest random update case, a node follows the majority with probability $(1 - \varepsilon)$, and it follows the minority with probability (ε) .
2. *Long axonal effects*: In neural populations, most of the connections are short, but there are relatively few long-range connections mediated by long axons. The effect of long-range axons is similar to small-world phenomena (Watts and Strogatz 1998).
3. *Inhibition*: The cortex contains excitatory and inhibitory connections. Inhibition contributes to the emergence of sustained narrow-band oscillations in the neural tissue. Inhibition is modeled by the interaction of excitatory and inhibitory populations in neuropercolation models.

Neuropercolation for Local, Mean Field, and Mixed Neighborhoods

Neuropercolation can have local, mean field, and mixed neighborhoods (Kozma et al. 2005). Local neighborhoods include the direct neighbors of the node in each dimension; e.g., in the 2-dimensional square lattice, the five neighbors are left/right, up/down, and the central node. In the mean field model, randomly selected grid nodes are used to define the neighborhood of a node, instead of considering specified local neighborhoods. Mixed models start with local neighborhood in a lattice and have a few local connections replaced

(rewired) by randomly selected connections from the whole lattice.

Mathematically rigorous description is possible in specific mean field models, where various conditions have been derived for stable fixed-point solutions and phase transitions between stable fixed points. It can be shown that there is a critical noise level (ε_0) with the following property (Balister et al. 2006), for

$$\varepsilon_0 \leq \varepsilon \text{ has one stable fixed point,}$$

$$\varepsilon_0 > \varepsilon \text{ has two stable and one unstable fixed points}$$

In the 2-dimensional squared lattice, $\varepsilon_0 = 7/30$. Let ρ denote the activation density of the nodes across the lattice. Near the critical point, the activation density (ρ) versus noise (ε) relationship approximates the following power law behavior with very good accuracy:

$$|\rho - 0.5| \propto (\varepsilon - \varepsilon_0)^\beta,$$

where $\beta = 0.5$ is the critical exponent. Similar scaling relationships are valid for the susceptibility (χ) and correlation length (ξ), as in Ising models (Binder 1981; Makowiec 1999):

$$|\rho - 0.5| \propto |\varepsilon - \varepsilon_0|^{-\gamma}, |\rho - 0.5| \propto |\varepsilon - \varepsilon_0|^{-\nu}.$$

Here γ and ν are the critical exponents of susceptibility and correlation length, respectively. Local and mixed models pose very difficult mathematical problems. In local models over finite lattices and for small noise ($\varepsilon \approx 0$), it has been proven that the system exhibits transitions between two metastable states in the following sense (Balister et al. 2010). It spends a long time at a high-density configuration and then rapidly transits to a low-density state, where it again resides for a long time. The transitions occur through some peculiar configurations, which can be considered as precursors of the phase transitions. For related concepts of “Dragon King” events, see Sornette and Quillon (2012).

Analytical solutions are not available for models with mixed neighborhoods describing

Neuropercolation and Neural Population Models, Fig. 1 Activation density in neuropercolation models with various levels of rewiring. The rewiring ratio is given as follows: *solid* no rewiring (local), *dash* 6.25%, *dotted* 25%, and *dash-dot* 100% rewiring (mean field). The horizontal dotted line at density = 0.5 level shows the unstable fixed point. (After Kozma et al. 2005)

long axon effects, and such systems are studied using Monte Carlo simulations (Puljic and Kozma, 2005). Figure 1 illustrates the simulation results for various neuropercolation models with local, mixed, and mean-field neighborhoods.

Higher-Order Neuropercolation Models

Multilayer neuropercolation models have been built for implementing hierarchical models of cortical populations (Freeman 1975; Freeman 2001; Kozma and Freeman 2009; Kozma and Puljic 2013). The results indicate that multilayer neuropercolation produces intermittent phase transitions resembling the ones observed in brains. Long axons communicating across mesoscopic cortical distances control the rapid switching from one pattern to another. The functional advantage of a network structure with overlapping hubs, similar to the observed “Rich Club,” has been analyzed based on the pioneer neurons concept (Bollobas et al. 2009; Zamora-López et al. 2011; Bullmore and Sporns 2012).

²Institut Universitaire en Santé Mentale de Québec and Department of Psychiatry and Neuroscience, Université Laval, Québec, Canada

Definition

Modelling ion fluctuations will permit better understanding of the role of perturbed ion homeostasis in the pathophysiology of nervous system diseases and will assist in guiding therapeutic interventions.

Detailed Description

The impact of ion channel gating has been modelled in great detail through colossal efforts invested by the neurocomputation community (Hines et al. 2004). However, understanding ion dynamics in itself bears equal importance as a crucial determinant of transmembrane currents.

Modulation and disruption of ion homeostasis plays a critical role in development, signaling, and in the pathophysiology of several diseases of the nervous system (De Koninck 2006). Since ion homeostasis is determined by the interaction between synaptic inputs, ion channels, and the activity of pumps and transporters, understanding the latter is of the utmost importance. These studies however raise many experimental difficulties because specific ion fluctuations are more difficult to measure than currents. Such difficulties in measurement have also slowed the development of models of ion homeostasis. Recently, improvements in measurement techniques such as the use of ion-sensitive dyes, time-resolved fluorescent measurements, and holographic microscopy to assess osmolarity have improved spatial and temporal resolution (Kaneko et al. 2013; Marquet et al. 2005). These have been paralleled by the development of new modelling techniques such as the use of finite element methods in neuroscience (Lopreore et al. 2008) spurring renewed interest in investigating ion dynamics as well as their functional impact.

Single-Compartment Model

Changes in mechanisms of ion regulation can translate into changes in ion concentrations as measured under resting conditions. For instance, a decrease in activity of the K^+Cl^- cotransporter KCC2 can be modelled by an accumulation of intracellular Cl^- ($[Cl^-]_i$), while the expression of carbonic anhydrase (CA) can be described by an increase in intracellular HCO_3^- (Rivera et al. 2005). However, this basic description fails to capture many consequences of perturbed ion homeostasis. Indeed, during development or in pathological pain, the effects of KCC2 hypofunction on Cl^- dynamics affects the rate and extent of the shift of Cl^- reversal potential (E_{Cl}) in response to overt Cl^- load, before any impact on baseline E_{Cl} can be measured (Cordero-Erasqui et al. 2005).

The simplest approach to describe ion dynamics is to reduce the neuron to a single spherical compartment and to extend the system of

differential equations describing electrical activity by including the ion concentrations as additional dynamic state variables. These supplementary variables are then needed to describe each ionic species considered. Single-compartment models can lead to nontrivial predictions such as the failure of drugs enhancing GABA_A-mediated activity to treat neuropathic pain in some conditions (Fig. 1; Asiedu et al. 2009; Doyon et al. 2011). Their simplicity also makes them amenable to use in network modelling, which has led to predicting that KCC2 activity may limit [K⁺]_o accumulation during epileptic seizures, contrary to what might be expected given that KCC2 normally extrudes K⁺ from the cell (Krishnan and Bazhenov 2011). Describing many ionic species rapidly leads to high-dimensional models which renders a full mathematical analysis of their solutions

intractable. Dimensionality reduction offers a promising approach to simplify multidimensional models while preserving the topologies of the solutions (Kepler et al. 1992).

The Multi-compartmental Approach

Single-compartment models fail to capture the impact of geometry beyond the radius of the soma and are limited to treat ionic concentrations as uniformly distributed. However, electrophysiology and Cl⁻-sensitive dye measurements have demonstrated the presence of functionally important intracellular concentration gradients (Doyon et al. 2011; Fig. 2). Such gradients can be permanent, result from differential expression of transporter, or can occur transiently after a focal

Neuropharmacological Modeling Alterations in Ionic Homeostasis, Fig. 1 Single-compartment modelling. (a) Schematic diagram showing how dynamic interactions between synaptic Cl⁻ influx and KCC2 Cl⁻ extrusion regulate [Cl⁻]_i. (b) Simulation of a neuron submitted to joint excitatory and inhibitory input. In a model using a

fixed E_{Cl} value, increasing inhibitory activity brings down ISR while the same leads to paradoxical excitation in a model accounting for dynamical Cl⁻ fluctuations. (c) Equations describing Cl⁻ fluctuations in a single-compartment model

cell at 13 days *in vitro*. (b) Values of [Cl⁻]_i as a function of distance from the center of the soma extracted from measurement in A. (c) A schematic diagram explaining the components of multi-compartmental modelling

synaptic activation. In either case, these gradients will have a significant impact on excitability and signaling (Baldi et al. 2010). An approach to simultaneously describe ion fluctuations in the soma, dendrites, and axon is to construct multi-compartmental models in which the neuron is divided in sections of simple geometry. The NEURON software has developed modules allowing the addition of ion dynamics to cable theory-based models offering a tool flexible enough to model chemical reactions playing a role in ion homeostasis such as Ca^{2+} buffering or CA-mediated HCO_3^- production. Multi-compartmental models have been used to study Ca^{2+} signaling and to investigate local Cl^- -mediated ionic plasticity (Raimondo et al. 2012).

Finite Element Modelling

Though very useful, multi-compartmental models fail to capture the impact of ionic fluctuations at submicroscopic scale and cannot accurately describe the complex geometries of neural substructures. The development of modelling tools free from these limitations is motivated by the following observations: (1) Spine geometry is believed to play a pivotal role in the integration of electrical signals (Yuste 2013; Fig. 3). (2) The high current density and small volume of nodes of Ranvier produce large ionic fluctuations – the resulting high density electric field may play a role in synchronizing electrical activity of axons (Yu et al. 2012). (3) Extracellular ionic fluctuations during a synaptic event play an important role in

signaling and may modulate the activity of presynaptic channels. The method of finite elements, which has been applied with great success to industrial problems, has also proven useful to study ion homeostasis in submicroscopic structures yielding a significant gain in precision when compared to cable theory models (Lopreore et al. 2008).

Treating ion concentrations as continuous quantities is valid only when the number of ions in each spatial element is large. When nanometric elements are considered or when micromolar Ca^{2+} concentrations are taken into account, simulations may lead to aberrant predictions such as fractions of ions being present in a nanodomain. Since modelling the displacement of individual ion is computationally impractical, hybrid methods and the use of partial derivative stochastic equations offer promising solutions (Modchang et al. 2010). One caveat of using fine spatial elements is that modelling a whole neuron can become computationally impractical, requiring the use of multi-scale modelling methods. Alternatively, the method of finite elements with adaptive meshes may be used to decrease computation time while preserving the quality of the solutions (Bois et al. 2012). Both approaches give rise to many technical challenges calling for collaboration between neuroscientists and applied mathematicians.

The Modelling of Pumps and Transporters

Ion fluctuations result from the activity of pumps and transporters, but the modelling of these

Neuropharmacological Modeling Alterations in Ionic Homeostasis, Fig. 3 Finite element method. (a) Diagram of stubby and mushroom-shaped dendritic spines. (b) Equations and meshes used in the finite element method. Here D stands for the diffusion coefficient, c for

concentration, $\alpha = 2 F/RT$, and $\beta = 2 F/\epsilon$, with ϵ being the electric permittivity of the medium. (c) Simulation results describing $[\text{Ca}^{2+}]$ accumulation (*top*) in the spine head during an AMPA event as well as dendritic EPSP (*bottom*) for the mushroom and stubby geometries

pumps and transporters also poses great challenges. For one, as opposed to ion flux through channels which may be characterized by a passive flux through an open pore, ion transport through pumps and exchangers is the end result of many steps consisting of ion binding, unbinding, and protein conformational changes. Models have been built to replicate each of these steps, yielding important mechanistic descriptions (Christiansen et al. 1983). An alternative approach is to model ion transport according to thermodynamic principles. To do so, one can compute the free energy associated with ion transport and assume that the level of transport is an increasing and saturating function of this free energy. Such simplification does not significantly compromise the accuracy of the model (Brumback and Staley 2008). Furthermore, in the case of KCC2, the rates of internalization, oligomerization, phosphorylation, and membrane localization can themselves depend on activity, making the level of active cotransporters likely to change with time (Puskarjov et al. 2012). To make accurate predictions on long time scales (minutes or hours), transition rates between cotransporter states should be understood and modelled.

In conclusion, modelling alterations in ion homeostasis is essential to understand pathologies and assess the potential efficacy of treatment strategies. For example, paradoxical pain resulting from chronic morphine treatment may be explained by ionic mechanisms (Ferrini et al. 2013). Understanding these mechanisms motivated the development of drugs acting directly to re-establish ionic homeostasis such as KCC2-positive modulators as potential therapeutics (Gagnon et al. 2013).

Neuropharmacological Modeling, Pharmacogenomics and Ion Channel Modulation

Tara Klassen and Tim T. Chen

Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, BC, Canada

Synonyms

[Channelopathy](#); [Drug effect](#); [Mechanisms of excitability](#); [Modifiers](#); [Pharmacogenomics](#)

Definition

Ion channels are both the primary cause of excitability disorders (e.g., epilepsy; myotonia; cardiac arrhythmia) and the principle target of many pharmaceutical compounds. Because ion channels

both respond to and regulate the cellular response to stimuli, they are the dominant molecules governing excitability of neurons and networks. Computational models of drug effects and genetic mutations reveal the mechanisms underlying channel function, allowing prediction to be validated in silico and generating new hypotheses that can be tested via biological experimentation.

Detailed Description

Ion channels containing an intrinsic ion permeable path can be broadly divided into two main functional categories, based on the mechanism by which they undergo the changes in protein conformation that opens or closes the ion permeation pathway (Sharman et al. 2013), allowing ions to flow down their electro-chemical gradient. Voltage-gated ion channels, like cationic potassium, sodium and calcium channels or anionic chloride channels, respond to changes in transmembrane voltage. In contrast, ligand-gated channels, frequently referred to as receptor channels, can be regulated by the extracellular binding of circulating or locally released molecules such as glycine, GABA, or NMDA, or by the binding of an intracellular molecule such as ATP (e.g., P2X), calcium (e.g., K_{Ca} or RyR), or sodium (e.g., K_{Na}).

Pharmacologically, ion channel function can be modulated by the interaction of pharmacophores with the site of activation: the ligand binding pocket or the transmembrane voltage sensing domain. They can also be modulated by direct steric occlusion of the ion permeation pathway. Importantly, the most deleterious of pathogenic mutations are generally located in these same critical regions of the channel protein. The degree of mutation and proximity to these critical sites are generally predictive of the severity of the clinical phenotype (Zuberi et al. 2011; Giudicessi et al. 2012).

Computational homology protein modeling, in combination with biological experimental data, offers insights into the mechanism of drug activity, and serve to identify amino acid residues integral to protein function, drug binding and pathological impact of disease-causing mutations

(Mullins et al. 2010). Many ion channel subfamilies share extensive identity and similarity in functional domains (Doupnik et al. 1995) but have distinct responses to pharmaceuticals (Furutani et al. 2009). *In silico* homology models can reveal those regions and specific residues responsible for pharmaceutical binding (Bertaccini et al. 2013; Verheij et al. 2012) and reactivity within the pore that respond biologically when mutated *in vitro* (Furutani et al. 2009). By understanding the mechanism of drug action and the protein structure responsible for enabling function, it is now possible to optimally design molecules with increased target affinity (Verheij et al. 2012), and these designer compounds can be used to correct pathophysiological states (Zhang et al. 2012). For example, a hERG channel (Kv12.1) activator was designed to potentiate the potassium channel delayed rectifier (I_{Kr}) current in *silico* and *in vitro* (Zhang et al. 2012). When applied to an iPSC-derived cardiomyocyte model of Long QT Syndrome, this molecule was able to correct the prolonged action potential duration resulting from a dysfunctional mutant Kv7.1 channel. This study highlights how molecules can be designed to elicit specific physiological reactions to treat excitable diseases.

Computational models populated with known ion channel biophysical properties measured experimentally can produce normally functioning neurons in *silico*. These models then provide a platform for establishing the mechanism of drug effect, and permit exploration of the contribution of ion channel activity to overall neuronal function. We can thereby begin to understand the basis of pharmacological activity, while elucidating essential ion channel components responsible for neuronal physiology observed *in vitro* in both normal and pathophysiological states. These models are also frequently used to isolate the contribution of an ion channel (sub)population to neuronal or network function (e.g., action potential generation, spike frequency), and to validate experimental results or generate testable hypotheses (Traub et al. 2003; John and Manchanda 2011; Martell et al. 2012; Shevtsova et al. 2011).

Many pharmaceuticals that have been shown to have an effect *in vivo*, have mechanisms of action and ion channel targets that remain

obscure. Development of models can help clarify these mechanisms, particularly in cases where a “dirty drug” has effects on multiple target channels. The development of these models requires an understanding of modulation and inhibition by pharmacological agents obtained from *in vitro* experimentation. Classical examples of such modulation are the complete block of voltage-gated sodium channel by TTX, or the enhanced activation of calcium-activated potassium channels (BK_{Ca}) by increased intracellular Ca^{2+} ion levels. By testing hypothetical targets in computation neuronal models, it is not only possible to identify likely candidate molecules but also to elucidate mechanisms of action (e.g., modulation of gating currents) which can then be confirmed by biological experimentation (Yau et al. 2010; Oh et al. 2012). Alternatively, the biological impact of pathogenic mutations and neuronal dysfunction can be modified in *silico*. These computational models of dysfunctional neurons can then be used to assess the efficacy of compounds (e.g., polyunsaturated fats, cAMP activators) or biological modifiers (e.g., ion channel accessory subunits) to correct nerve cell pathology (Tigerholm et al. 2012; Tigerholm and Fransén 2011).

Ultimately, the utilization of computational models as an extension of biological experimentation, and as a platform for validating or resolving competing hypotheses of ion channel function and modulation, enhances our comprehension of the mechanism of activity of both intrinsic and extrinsic ion channel targeting molecules. By generating models of both the normal and pathophysiological states, it is possible to optimally design molecules to combat or cure disease through reduction or enhancement of specific neuronal function in targeted neuron populations.

Neuroscience Information Framework (NIF)

Maryann E. Martone¹ and Anita Bandrowski²

¹Department of Neuroscience, University of California, La Jolla, CA, USA

²NIF Project Lead, University of California, San Diego, La Jolla, CA, USA

Detailed Description

The Neuroscience Information Framework (NIF; <http://neuinfo.org>; Gardner et al. 2008) is currently managed, maintained, and hosted by researchers in the Center for Research in Biological Systems (CRBS) at the University of California, San Diego. The NIF system has grown since 2008 from a modest catalog of 300 resources

developed during the first phase of NIF to the largest source of neuroscience resources on the web. As defined here, resources include data, databases, software/web-based tools, materials, literature, networks, or information that would accelerate the pace of neuroscience research and discovery.

The current NIF system was developed to provide practical approaches for finding, searching, and integrating biomedical resources of relevance to neuroscience, including:

- A biomedical resource catalog for both data and tools (Cachat et al. 2012).
- A public-federated biomedical data repository (Fig. 1)
- An ontology for neuroscience (Imam et al. 2012).
- A unique and flexible technology platform for finding and sharing resources, undergirded by

an advanced semantically enhanced search system

- Text mining tools for resource identification and tracking in the biomedical literature (Bandrowski et al. 2012).
- Tools and services for easy sharing of data and linking of data to articles, websites, etc. (Marenco et al. 2008).

History of NIF

The NIF project started in 2006 under the leadership of Dr. Dan Gardner at Weill Medical College of Cornell University as an initiative of the NIH Blueprint consortium. NIF was tasked with surveying the neuroscience resource landscape and to develop a resource description framework and search

Neuroscience Information Framework (NIF), Fig. 1 NIF discovery portal showing search results from the data federation (left) and from a specific resource (right)

strategy for locating, accessing, and utilizing these resources. Most of these resources were created through significant investment of government dollars but remained largely unknown or underutilized by the research community they were created to serve. The first phase of the NIF, completed in 2008, resulted in the first version of the NIF Registry, a catalog of neuroscience-relevant resources annotated with a controlled vocabulary covering multiple dimensions (e.g., organism, nervous system level, and resource type).

UCSD assumed leadership of the project in 2008, leading a consortium of five universities in the creation of the current NIF system. Based on the initial survey, it was apparent that most resources, particularly databases, were not adequately searched through a simple metadata scheme but required deeper access. In addition, most of these data sources were part of what is known as the “hidden web,” that is, content that is not readily accessible to search engines like Google. It was also apparent that the simple controlled vocabulary developed for resource curation during the first phase was not adequate to support the diversity of resources or neuroscience concepts in a way that promoted search.

Based on this requirement, the NIF system expanded from a simple catalog, with high-level metadata on resource type and coverage, to a comprehensive system that allowed deeper registration of individual data resources through innovative data federation technologies as well as identification of resources from the primary biomedical literature. During this phase, the NIF registry grew from a registry of 300 resources and 5 federated databases to over 6000 resources and 200 federated databases and data resources, amassing the largest searchable collection of biomedical data on the Internet (Cachat et al. 2012). NIF also developed the NIFSTD ontologies, a set of community ontologies implemented in OWL covering the major domains of neuroscience which were assembled from existing ontologies in use in the broader life science community but enhanced with neuroscience-specific content. The NIFSTD ontologies are used to provide a semantic framework for searching and annotating diverse content.

Mission

The NIF has as its mission to provide added value to existing biomedical resources by increasing their accessibility, visibility, utility, and interoperability, regardless of their current design or capabilities and without the need for extensive redesign of their components. As NIF has documented in its Resource Registry, there are thousands of resources made available through the Internet that are relevant to neuroscience research. However, despite the availability and increasing power of Internet search engines, these types of resources continue to be difficult to find and access. NIF provides a uniform access point for searching across and within these digital resources, with a special emphasis on databases. To accomplish this, NIF deploys an infrastructure that allows resources to be searched and discovered at multiple levels of integration, from superficial discovery based on a limited description of the resource to deep content query through the NIF federation services. The NIF has adopted a federated model whereby resources are developed and maintained independently but through the use of central indices, distributed query capabilities, and an extensive ontology for neuroscience, they can be cross-queried and integrated into a unified system. NIF provides a portal to resource discovery whereby these different web-accessible resources, along with the published literature, may be searched and also provides a set of tools and services that promote interoperability among resources, including the NIF vocabularies and a brokering service linking resources together.

Overview of NIF Infrastructure and Current System

NIF's infrastructure comprises four primary modules: resource management and data ingestion, index management, semantic information management, and data access and analysis. NIF employs a combination of user contribution and automated discovery, including text mining of the literature, to continually discover web-accessible resources that are relevant for neuroscience. Descriptions of these resources are maintained in

Neuroscience Information Framework (NIF), Fig. 2 NIF integrated view for nervous system connectivity: showing search results for the Ca2 field of the hippocampus. Note that the semantic expansion includes terms that users did not specifically ask for, but are synonyms of the user's term (*top arrow*). The result set comes from BAMS (Brain Architecture Management System),

TemporalLobe.com, and the CoCoMac database. All fields have been aligned and projection strength has been mapped to one of seven values. In the case that the original terminologies were not easily interpretable as brain regions, they were translated (*bottom blue arrow* from CoCoMac shows the source data labels for the accessory basal nucleus and the CA2 subfield of Ammon's horn)

the NIF Registry. For those resources that share their data, automated agents, via the DISCO dashboard (Marenco et al. 2008), automatically retrieve the latest data from these selected resources to ensure that information contained within NIF is current. The environment also allows new data resources to be added to the system with an interface for registering core information about the data resource and annotating the data/resource with ontology terms to declare the semantic relationships contained therein.

Semantic Infrastructure

NIF has created a semantic infrastructure for biomedical information, meaning that any data resource should be accessible by its content and the concepts it represents. This means any biomedical researcher should be able to discover a resource regardless of how the original resource and its data were modeled and structured or how a specific term was spelled or described. This mandate was challenging because it was not only

important to have a standardized vocabulary with synonyms, but the entire system from data ingestion to search services needed to be aware of the semantics of the data (Fig. 2).

NIF Integrated Views

Within the resources in the NIF Data Federation, there are collections of data that cover the same theme. In these cases, NIF provides an integrated view across similar resources to make it easier to align and compare different resources of the same type (Fig. 2). Some examples include NIF Connectivity, a view across six different connectivity databases (see figure above); NIF Animal, primarily transgenic animals available for sale (or by material transfer agreement); and NIF Software, contents of several software repositories designed for neuroscience and for the software branch of the NIF Registry.

NineML

Andrew P. Davison

Unité de Neurosciences, Information et Complexité (UNIC), Institut de Neurobiologie Alfred Fessard, Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Synonyms

[9ML](#)

Definition

NineML is a markup language for describing neuronal network models. It is intended to provide a mechanism for scientists to publish and share unambiguous, mathematically explicit model definitions, with the aims of promoting reproducibility and reusability of components. NineML has a two-layered architecture, with an “abstraction” layer that is used to define mathematically the behavior of components, such as neurons, synapses, and connectivity rules and a “user” layer that is used to specify network structure in terms of populations of neurons and the projections between them, on the basis of the components described in the abstraction layer.

Detailed Description

NineML is defined in terms of an object model. The current specification is available at <http://software.incf.org/software/nineml/wiki/nineml-specification>. The canonical serialization of this object model is as an XML document, but

NineML documents can also be created using a domain-specific language (NineML “native” syntax) and using a Python API.

Figure 1 shows a simple abstraction layer example that defines an integrate-and-fire neuron. The NineML abstraction layer dynamics module defines two principal objects, Regimes and Transitions. Each Regime defines a number of ordinary differential equations. The model can be in only one Regime at a time and remains in that Regime until either some condition is met (e.g., one of the state variables passes some threshold) or an external event arrives (e.g., an action potential from another neuron). At this point, a Transition occurs to the same or some other Regime, during which state variables may be changed discontinuously and events emitted. Components can expose state variables or derived variables through Ports, which allow components to be connected together (e.g., synapse models and neuronal membrane models) and to send or receive events. The integrate-and-fire neuron has two Regimes, one describing the usual behavior of the neuron, in which the membrane is depolarized by injected or synaptic currents, the other describing the refractory behavior after a spike, in which the membrane potential is clamped to a fixed

value. Detection of the threshold crossing, reset of the membrane potential, and emission of a spike event is described by one Transition, the end of the refractory period by another.

The NineML project was initiated by the International Neuroinformatics Coordinating Facility (INCF) Program on Multiscale Modeling, originally developed by an INCF taskforce, and is now developed as a community-based project at <https://github.com/INCF/nineml>.

NineML has considerable overlap with ► NeuroML version 2 (<http://www.neuroml.org/>) and the LEMS language (<http://www.psics.org/lems/>), with LEMS corresponding roughly to the NineML abstraction layer and NeuroML to the user layer.

SpineML (<http://bimpa.group.shef.ac.uk/SpineML/>) is a derivative of the NineML language that adds a third layer, for description of simulation experiments. SpineML uses XSLT to provide code-generation for several simulation platforms.

Nitric oxide volume signaling

Definition

Neuromodulators are a class of neurotransmitter that diffuse into the region surrounding an emitting neuron and affect potentially large numbers of other neurons by modulating their responses, irrespective of whether or not they are electrically connected to the modulating neuron. Nitric oxide (NO) is a particularly interesting example of a neuromodulator because of its very small size and gaseous state. The type of modulatory signaling NO is involved in is sometimes known as volume signaling and is in sharp contrast to the connectionist point-to-point electrical transmission picture that dominated thinking about the nervous system for many decades, whereby neural signaling could only occur between synaptically connected neurons.

Detailed Description

Background

The discovery that the toxic gas nitric oxide (NO) is synthesized in biological systems and functions as a physiological signaling molecule earned Robert Furchgott, Louis Ignarro, and Ferid Murad the Nobel Prize in 1998. By showing that physiological functions could be regulated by information carried from cell to cell by a gas, their research suggested an entirely new way of

thinking about how cells communicate with one another.

Increasing blood flow was the first physiological function attributed to NO. It was known that the cells of the endothelial lining of blood vessels released a factor which caused the relaxation of circular muscle leading to vessel dilation and increased blood flow. The endothelial factor was unstable and thus elusive. But the combined work of the three Nobel laureates showed conclusively, if unexpectedly, that this factor was NO.

If this were the whole story, there would be of little or no relevance for our understanding of brain function. When, however, Solomon Snyder and colleagues isolated an enzyme from the mammalian brain that synthesized NO and showed that it was present in subpopulations of neurons (Bredt and Snyder 1990), interest in NO's signaling functions switched from endothelial cells to neurons.

Three forms of the NO-synthesizing enzyme, known as NOS, have been identified; it is the neuronal form (nNOS) which attracted most interest among neuroscientists (Bredt and Snyder 1990; Bredt et al. 1990; Mungrue and Bredt 2004). Since NO is both a signaling molecule and a toxic-free radical gas, its generation by nNOS must be strictly controlled. The primary regulator of nNOS activity is the concentration of calcium inside the nNOS-expressing neurons (Bredt and Snyder 1990). Intracellular calcium concentration in resting neurons is very low – below that required for the synthesis of NO. However, as a consequence of electrical activity, calcium enters the neuron via voltage-gated calcium channels, and the concentration rises transiently from micromolar to millimolar levels. At these elevated levels, the synthesis of NO is triggered. Calcium therefore neatly links the synthesis of NO in the brain to the electrical activity of neurons. Because NO is so small (the tenth smallest molecule of the universe) and non-polar, it can diffuse more or less freely away from its source, unimpeded by the lipid bilayer of the cell membrane. Thus, for NO, release is an inevitable consequence of NO synthesis.

Calcium influx in electrically excited neurons both triggers NO release and the release of conventional neurotransmitters from synaptic

vesicles. The two modes of release, diffusive and vesicular, are not mutually exclusive alternatives at the neuronal level. Neurons capable of NO synthesis also store conventional neurotransmitters in synaptic vesicles. NO is therefore best regarded as a co-transmitter, acting in conjunction with classical inhibitory and excitatory transmitters.

Clearly NO signaling violates some of the classical tenets of synaptic transmission, and there has been an understandable reluctance to regard NO as a genuine neurotransmitter. Perhaps the term neuromodulator is more appropriate. Neuromodulators are a class of neurotransmitter that, rather than causing excitation or inhibition directly, modulate the responses of neurons to direct excitatory and inhibitory transmitters. A modulator may, for example, enhance or facilitate the inhibitory effect of an inhibitory neurotransmitter. In this way modulators are synaptic gain-control agents. Whereas direct inhibition and excitation is mediated by transmitter-gated ion channels, modulators bind to receptors that regulate the synthesis of the so-called second messengers, and it is these that can change the sensitivity of a neuron to other neurotransmitters.

Because they act indirectly via a neuron's metabolic machinery, the temporal dynamics of neuromodulator effects are delayed and more long-lasting than the quick and transient effects of the classical transmitters. The spatial dynamics of neuromodulation are also noteworthy with respect to signaling by NO. As noted above, the physical properties of NO allow it to diffuse into the volume surrounding an emitting neuron. Therefore, depending on the size of the affected volume, a NO-emitting neuron may modulate large numbers of other neurons within the affected volume. Importantly then, an nNOS-expressing neuron may communicate with other neurons irrespective of whether or not they are connected by synapses. In this way NO is a particularly interesting example of a neuromodulator because it can act as a non-synaptic volume signal. This clearly is in sharp contrast to the connectionist point-to-point synaptic transmission picture that dominated thinking about the nervous system for many decades.

In the traditional connectionist model of neuron-to-neuron communication, neurons generate brief electrical signals (action potentials), which propagate along wire-like axons terminating at highly localized junctions (synapses) on other neurons, where the release of a neurotransmitter is triggered. The neurotransmitter is confined to the region of the synapse, and here the receiving neuron is equipped with receptors that directly translate the chemical signal into a brief electrical signal, either excitatory or inhibitory (Purves 1997; Brazier 1961). Hence, in standard artificial neural network (ANN) models based on this incomplete picture, chemical signaling can be safely factored out, leaving only the idea of electrical signals flowing between nodes in a network.

However, the discovery of non-synaptic chemical signaling by NO has potentially greatly extended the spatial scale over which neurons can communicate. The most important feature of this derives from the ability of NO to diffuse away from its site of release and to occupy a volume of the nervous system perhaps containing many other neurons and synapses (Edelman and Gally 1992). Crucial to understanding the functional significance to volume signaling by NO (and perhaps other gases) is a measure of the spatial and temporal dynamics of NO diffusion. We need to know how large is the affected volume and how long does it take for NO to occupy it. As these questions have proven to be difficult to answer empirically (Philippides et al. 2003), an important alternative approach has been to develop realistic computational models of diffusion to illuminate the parameters of NO-mediated volume signaling.

The following section looks at how NO diffusion in the nervous can be modeled computationally and how this can be used to illuminate neuromodulatory mechanisms. We will also explore how volume signaling can now be added to the growing list of phenomena in the nervous system that might be a source of inspiration for new and perhaps improved styles of ANNs. This is probably especially true for ANNs intended for use as artificial nervous systems in robots or simulated autonomous agents, an area where biomimetic techniques are often particularly fruitful. Classes of ANN directly inspired by NO

signaling, which can be used in robotic applications or to shed light on biological questions, will be discussed later in this article.

Modeling NO Diffusion in the Nervous System

The features that make NO different to a standard neurotransmitter – its free diffusion through neural structure with no discrete target receptor and thus inactivation – make the basis of a model relatively straightforward. Movement is governed by Fick's second law of diffusion; essentially molecules move from high concentration to low concentration. NO does not have a specific inactivating mechanism and is lost through reaction with oxygen species and metals as well as with heme-containing proteins (Lancaster 1996; Vaughn et al. 1998a). This means that the movement of other molecules and receptors and their interactions need not be modeled and instead a more general loss function can be used, typically as concentration-dependent decay throughout the volume being modeled. These features were the basis of the first wave of models of diffusion (Gally et al. 1990; Edelman and Gally 1992; Montague et al. 1991; Lancaster 1994, 1996, 1997; Wood and Garthwaite 1994) which prompted key insights into the action of this kind of messenger, for instance, noting it as a “four-dimensional volume signal” (Edelman and Gally 1992), and highlighting the potential range of action of a diffusible signal (e.g., Wood and Garthwaite 1994).

To make these general points, it was not important to model in detail the structure of either the volume within which the neuron was diffusing (meaning that space and time were typically handled coarsely) or the source neuron itself which was typically taken to be a point in space. This meant they were unable to capture two very important features of NO signaling.

The first regards the production of NO and follows from the fact that nitric oxide synthase (NOS, responsible for the production of NO) is soluble and thus highly likely to be distributed throughout a neuron's cytoplasm. This means

that the volume containing NOS is the source and the whole surface of the neuron is a potential release site for NO, in marked contrast to conventional transmitter release. These properties suggest that the 3D structure of the NO source will have a profound influence on the dynamics of NO spread. Hence, an accurate structure-based model of neuronal NO diffusion is an indispensable tool in gaining deeper insight into the signaling capacity of the molecule. The second is that depletion of NO might also be spatially heterogeneous. While a general decay rate can be assumed for most tissue, reflecting background oxidization and binding events, certain structures (importantly including blood vessels containing very high concentrations of NO-binding hemes) can have a much higher decay rate and effectively act as NO sinks. The kinetics of these reactions are not understood perfectly (Wood and Garthwaite 1994), but empirical data indicates either first- or second-order decay (Laurent et al. 1996; Lancaster 1996; Vaughn et al. 1998b; Liu et al. 1998; Thomas et al. 2001).

These considerations gave rise to a second set of more detailed NO diffusion models (Philippides et al. 1998, 2000, 2005a; Vaughn et al. 1998a, b; Ott et al. 2007) based on the modified diffusion equation shown in Eq. 1. The terms on the left-hand side describe the general diffusion process and those on the right-hand side model NO production and depletion mechanisms:

$$\begin{aligned}\frac{\partial C(\mathbf{x}, t)}{\partial t} &= D \nabla^2 C(\mathbf{x}, t) \\ &= P(\mathbf{x}, t) - \lambda C(\mathbf{x}, t) \\ &\quad - S(\mathbf{x})(C(\mathbf{x}, t))^n\end{aligned}\quad (1)$$

where $\mathbf{x}$ is a point in space; $C(\mathbf{x}, t)$ is the concentration at point $\mathbf{x}$ and time t ; D is the diffusion coefficient, typically $3300 \mu\text{m}^2 \text{s}^{-1}$; and $P(\mathbf{x}, t)$ is the concentration of NO produced per second at point $\mathbf{x}$ and time t . $\lambda C(\mathbf{x}, t)$ models background inactivation of NO at all locations in the modeled volume as first-order decay with an inactivation rate (half-life) of λ . In contrast, $S(\mathbf{x})(C(\mathbf{x}, t))^n$ models spatially localized NO sinks such as blood vessels where the decay rate is greatly elevated within a discrete region. Decay can be

modeled as first order ($n = 1$) or second order ($n = 2$), though the latter is mainly used for very strong blood flow such as when modeling diffusion of NO from endothelial cells surrounding large blood vessels (Vaughn et al. 1998a, b).

Armed with these equations, the time course of NO diffusion from neurons of different shapes and sizes was modeled in the presence of different levels and types of decay. Figures 1 and 2 show the results generated by the first accurate model of NO diffusion from a continuous biologically realistic structure (Philippides et al. 1998, 2000, 2003). The source was a large neuron-like structure modeled as a hollow sphere as NO is synthesized throughout the cytoplasm but not in the nucleus. In this case, there are no sinks and thus $S(\mathbf{x}) = 0$ in Eq. 1 and decay rate λ is set so that the NO half-life is 5 s. $P(\mathbf{x}, t)$ is a constant value for all points inside the hollow spherical source during synthesis (the amount of NO produced per second by a single NO-producing unit multiplied by the density of these units) and 0 elsewhere, and thus

the solution is radially symmetric. (For full details of modeling methods and biological justification for parameter values, see Philippides et al. 2000, 2003, 2005a).

Examination of the time course of the evolution of NO concentration during and after 100 ms of NO synthesis shows two very interesting observations. Firstly, the NO concentration remains elevated within and throughout the cell for significant lengths of time after the end of synthesis: a “reservoir” effect (Fig. 1). Second, when viewed over time, there is a delay before the concentration peaks at points where NO is not synthesized, both within the neuron itself and outside it (Fig. 2). Further, the delay increases, while peak concentration decreases, with distance from the NO source neuron. To determine the volume affected by NO, we would need to know the physiologically effective NO concentration, which is likely to vary depending on a number of factors. However, taking a threshold of 0.1 μM (close to the equilibrium dissociation constant for the NO

Nitric Oxide Neuromodulation, Fig. 1 Concentration of NO plotted against distance from the center of a hollow spherical source neuron of inner radius 50 μm and outer radius 100 μm for a 100 ms burst of synthesis starting at time $t = 0$. The graphics underneath each plot depict the source structure. (a) Concentration of NO at times $t = 25$, 50, and 100 ms, two time points during and one at the end

of synthesis. (b) Concentration of NO after synthesis at times $t = 175$, 300, and 1.5 s. The reservoir effect following the end of synthesis is clearly seen as the centrally accumulated NO is trapped by the higher surrounding concentrations. (Figure used with permission from Philippides et al. 2000)

Nitric Oxide Neuromodulation, Fig. 2 Concentration of NO plotted against time after synthesis for a hollow spherical source of inner radius 50 μm and outer radius 100 μm for a 100 ms burst of synthesis. Here the *solid line* depicts the concentration at the center of the cell (0 μm), while the *dotted line* shows the concentration at 225 μm from the *center*. Because the absolute values attained at the two positions differ from one another markedly, the concentration is given as a fraction of the peak concentration attained. These peak values are 7.25 μM (*center*) and

0.25 at 225 μm . The cell and the points at which the concentration is measured are depicted to the *left* of the main figure. Note the high central concentration, which persists for a long time (above 1 μM for about 2 s). Also, there is a significant delay to a rise in concentration at distant points which is more clearly illustrated in the expanded inset figure. The square-wave beneath the inset figure represents NO synthesis. (Figure used with permission from Philippides et al. 2000)

receptor soluble guanylyl cyclase, Stone and Marletta 1996), with 100 ms of NO synthesis within the walls of hollow spherical neurons with radii over 10 μm , a volume approximately three times the source radius would be affected. Although, importantly, the concentration time course would depend on distance from the source. While spatially localized NO sinks such as small blood vessels do affect diffusion, they do not alter these overall properties (Philippides et al. 2000).

In many instances, however, NO is not produced in one source but in multiple distinct sources. For instance, the mushroom bodies (MB) of the locust (*Schistocerca gregaria*) are composed of parallel axons of intrinsic neurons

(Kenyon cells, KCs) arranged in a tubular structure in which peripheral NOS-positive KC axons form NO-producing zones, the tube “walls,” surrounding central cores of NO-receptive KC axons, which do not produce NO. This segregated architecture requires NO to spread at physiological concentrations up to 60 μm from the outer regions of the tube where it is synthesized to the target axons in the inner NO-receptive cores (Fig. 3). Despite NO being produced by small numbers of distinct sets of KCs in response to odors and that single KCs in the tube walls cannot produce enough NO to generate effective signals in the central targets, they act cooperatively and a reservoir of NO builds up in the NOS-negative cores.

Nitric Oxide Neuromodulation, Fig. 3 Sparse activity in the nitric oxide (NO) synthase (NOS)-positive *outer* region of the mushroom body (MB) yields a strong volume signal in the NOS-negative core. The MB is made up of a parallel array of 30,525 Kenyon cell axons represented as 0.5 μm diameter fibers within a tubular region of 99 μm diameter. Axons within the inner 33 μm diameter tubular core of the MB are NOS negative and designated as targets. The remaining 27,212 NOS-positive axons form an annular “wall” (shown as a *dark gray* cutout in the *upper* part) around the core and are potential NO sources. In

10 independent runs of the diffusion model, a random 5% of these peripheral NOS-expressing Kenyon cell axons in the tube wall synthesize NO simultaneously for 50 ms. NO half-life is 5 s though results are qualitatively similar for other values. The resultant NO concentrations are shown along a line through the center of the stalk as 10 superimposed plots (*upper* part) and, for a single run, in a cross-section through the MB (*lower* part) at the end of synthesis, 50 and 200 ms later. (Figure used with permission from Ott et al. 2007)

N

During synthesis, NO is highest in the tube walls containing the NOS-positive axons, and the resulting concentration gradient drives NO into the center where it accumulates. About 50 ms after the end of synthesis, the peak concentration is in NOS-negative cores where NO remains locally elevated for several 100 ms. Further, NO signals in the core of the MB are highly invariant for a given percentage of randomly selected active sources. Importantly, the general features of the diffusion dynamics illustrated here are unaffected by the strength or duration of the synthesis pulse, showing that an effective volume signal can be produced by segregated small sources.

Such cooperative volume signaling can again be seen in a model of NO production in the optic lobe of the locust (Fig. 4). Here NO is again produced in multiple distinct fine fibers of approximately 2 μm diameter. As with the locust mushroom body, despite a single fiber producing an ineffective concentration, NO from multiple fibers summate to produce effective concentrations over large regions (Fig. 4a, b). This is also the case if sources are arranged irregularly instead of in parallel arrays and if their firing is asynchronous. Finally, the volume signal persists despite large changes to the parameters governing diffusion, namely, the half-life of NO, $t_{1/2}$, and the diffusion

coefficient, D . When half-life is reduced to 100 ms (Griffiths and Garthwaite 2001), 1/50 of the value used in Fig. 4a, the concentrations in the target volume fall to only approximately one-third

(250–475 vs. 700–1300 nM). Further reduction of $t_{1/2}$ to 10 ms yields a more spiky concentration distribution with 100 nM peaks at the fibers. However, at least 50% or more of this peak

Nitric Oxide Neuromodulation, Fig. 4 Cooperative volume signals produced by ordered arrays of parallel NO-synthesizing fibers at the end of a 1 s burst of NO synthesis. Fiber diameters (2 μm) and spacing (10 μm) approximate that in the locust optic lobe (Elphick et al. 1996). (a) NO concentration in slices across increasing numbers of active fibers (white dots). A single fiber is a relatively ineffectual NO source (1 fiber in a), but increasing numbers (4–36 fibers) result in cumulative buildup of NO. (b) As the number of fibers increases, so does the

volume of tissue over a particular concentration, here 100 nM. NO half-life $t_{1/2}$ is 5 s in a and b. (c) The cooperative volume signal is robust to variation in NO half-life $t_{1/2}$ within the limits reported in the literature, from top to bottom $t_{1/2} = 10, 100$, and 500 ms. (d) Strong cooperation is still observed when $t_{1/2}$ is relatively short (100 ms) and D is reduced to $1100 \mu\text{m}^2\cdot\text{s}^{-1}$, one-third of its standard value. (Figure used with permission from Philippides et al. 2005a)

concentration is still reached everywhere throughout the target volume. Similarly, while reducing the speed of diffusion dramatically by decreasing D to a third of its standard value and using a relatively short half-life, $t_{1/2} = 100$ ms, means that the spread of the volume signal outside of the source array is limited (compare Fig. 4d with bottom middle of Fig. 4a), a strong cooperative volume signal is still observed within the array.

The examples in Figs. 3 and 4 show that small discrete NO sources can act to produce a cooperative volume signal, despite asynchronous activity and irregular arrangement and spacing. In these contexts, the diffusion process can be seen as a spatiotemporal integrator of neural activity in discrete sources. Interestingly, while the two features seen in large continuous sources still exist – concentrations within the source neurons persist after the end of synthesis and central concentrations can peak after synthesis has ended – there is one key difference. With these dispersed sources, the dynamics of diffusion mean that the concentration quickly becomes quite uniform within and close to the volume containing the NO sources. This means that if the goal of the signaling system is to produce an even concentration within a volume, this is best achieved with a network or plexus of fine NO-producing fibers, perhaps giving rise to a different type of volume signal (explored in abstract form in the plexus GasNet model described below and in Philippides et al. 2005b). In turn this work led to further theoretical and empirical investigations that have provided experimental evidence for the kind of cooperative signaling predicted by the models described above (Steinert et al. 2008).

GasNets: NO-Inspired ANNs

Detailed models of long-range neurotransmitter diffusion in the nervous system are necessarily computationally expensive so the use of such models in the study of whole behavior-generating circuits has so far been beyond the state of the art. Hence, to further investigate the functional roles of volume signals and related mechanisms in the generation of behavior, a number of authors have

advocated the study of more abstract artificial robot nervous systems incorporating simplified models of volume signaling and related processes (Grand 1997; Husbands et al. 1998; Kondo et al. 1999; Eggenberger et al. 2000; Kondo 2007; Buckley 2008). These systems are computationally tractable and can generate sensorimotor behaviors in real time in simulations or in the real world.

This section describes a style of artificial neural network directly inspired by NO neuromodulation, making use of an analogue of volume signaling. The class of artificial neural networks developed to explore artificial volume signaling are known as GasNets (Husbands et al. 1998). These are essentially standard neural networks augmented by a chemical signaling system comprising a diffusing *virtual* gas which can modulate the response of other neurons. As outlined below, a number of GasNet variants, inspired by different aspects of real nervous systems, have been explored in an evolutionary robotics (Floreano et al. 2008) context as artificial nervous systems for mobile autonomous robots.

Evolutionary robotics involves populations of artificial genomes (lists of characters and numbers, the members of which act as “genes”) which encode the structure and other properties of artificial neural networks that are used to control autonomous mobile robots required to carry out a particular task or to exhibit some set of behaviors. Other properties of the robot, such as sensor layout or body morphology, may also be under “genetic” control. The genomes are mutated and interbred creating new generations of robots according to a Darwinian scheme (i.e., an evolutionary search algorithm) in which the fittest individuals are most likely to produce offspring. Fitness is measured in terms of how well a robot behaves according to some evaluation criteria; this is usually automatically measured. Evolutionary robotics can operate with fewer assumptions about neural architectures and behavior-generating mechanisms than other methods; this means that whole general classes of designs and processes can be explored (Floreano et al. 2008; Vargas et al. 2014). This makes it a particularly attractive technique for synthesizing models in

neurobiology, allowing explorations of possible processes and mechanisms as in the work described here (Flozano et al. 2008).

GasNets have been shown to be significantly more evolvable, in terms of speed to a good solution, than other forms of neural networks for a variety of robot tasks and behaviors (Husbands et al. 1998; McHale and Husbands 2004; Smith et al. 2003; Philippides et al. 2005b). They are being investigated as potentially useful engineering tools and as a way of gaining helpful insights into biological systems (Philippides et al. 2000, 2003, 2005b; Husbands et al. 2010).

By analogy with biological neuronal networks, GasNets incorporate two distinct signaling mechanisms, one “electrical” and one “chemical.” The underlying “electrical” network is a discrete time step, recurrent neural network with a variable number of nodes. These nodes are connected by either excitatory or inhibitory links with the output, O_i^t , of node i at time step t determined by the following equation:

$$O_i^t = \tanh \left[k_i^t \left(\sum_{j \in \Gamma_i} w_{ji} O_j^{t-1} + I_i^t \right) + b_i \right]$$

where Γ_i is the set of nodes with connections to node i and $w_{ji} = \pm 1$ is a connection weight. I_i^t is the external (sensory) input to node i at time t and b_i is a genetically set bias. Each node has a genetically set default transfer function gain parameter, k_i^0 , which can be altered at each time step according to the concentration of diffusing “gas” at node i to give k_i^t (as described later).

In addition to this underlying network in which positive and negative “signals” flow between units, an abstract process loosely analogous to the diffusion of gaseous modulators is at play. Some units can emit virtual “gases” which diffuse and are capable of modulating the behavior of other units by changing their transfer functions. The networks occupy a 2D space; the diffusion processes mean that the relative positioning of nodes is crucial to the functioning of the network. Spatially, the gas concentration varies as an inverse exponential of the distance from the emitting node with spread governed by a parameter, r , genetically set for each node, which governs the

radius of influence of the virtual gas from the node as described by the equations below and illustrated in Fig. 5. The maximum concentration at the emitting node is 1 and the concentration builds up and decays linearly as dictated by the time course function, $T(t)$, defined below:

$$C(d, t) = \begin{cases} e^{-2d/r \times T(t)} & d < r \\ 0 & \text{else} \end{cases}$$

$$T(t) = \begin{cases} 0 & t = 0 \\ \min \left(1, \left(T(t-1) + \frac{1}{s} \right) \right) & \text{emitting} \\ \max \left(0, \left(T(t-1) - \frac{1}{s} \right) \right) & \text{not emitting} \end{cases}$$

where $C(d, t)$ is the concentration at a distance d from the emitting node at time t and s (controlling the slope of the function T) is genetically determined for each node. The range of s is such that the gas diffusion timescale can vary from 0.5 to 0.09 of the timescale of “electrical” transmission (i.e., a little slower to much slower). The total concentration at a node is then determined by summing the contributions from all other emitting nodes (nodes are not affected by their own emitted gases to avoid runaway positive feedback). The diffusion process is modeled in this simple way to provide extreme computational

A GasNet. Neuron 3 is emitting gas, and modulating neuron 2 despite there being no synaptic connection.

Nitric Oxide Neuromodulation, Fig. 5 A basic GasNet showing excitatory (solid) and inhibitory (dashed) “electrical” connections and a diffusing virtual gas creating a “chemical” gradient

efficiency, allowing arbitrarily large networks to be run very quickly.

For mathematical convenience, in the original basic GasNet, there are two “gases”: one whose modulatory effect is to increase the transfer function gain parameter (k_i^t) and one whose effect is to decrease it. It is genetically determined whether or not any given node will emit one of these two gases (gas 1 and gas 2) and under what circumstances emission will occur (either when the “electrical” activation of the node exceeds a threshold or the concentration of a genetically determined gas in the vicinity of the node exceeds a threshold; note that these emission processes provide a coupling between the electrical and chemical mechanisms). The concentration-dependent modulation is described by the following equation, with transfer function parameters updated on every time step as the network runs:

$$k_i^t = k_i^0 + \alpha C_1^t - \beta C_2^t$$

where k_i^0 is the genetically set default value for k_i ; C_1^t and C_2^t are the concentrations of gas 1 and gas 2, respectively, at node i on time step t ; and α and β are constants such that $k_i^t \in [-4, 4]$. Thus, the gas does not alter the electrical activity in the network directly but rather acts by continuously changing the mapping between input and output for individual nodes, either directly or by stimulating the production of further virtual gas. The general form of diffusion is based on the properties of a (real) single source neuron as modeled in detail in Philippides et al. (2000, 2003). The modulation chosen is motivated by what is known of NO modulatory effects at synapses (Baranano et al. 2001). For further details, see Husbands et al. (1998), Philippides et al. (2005b), and Husbands et al. (2010).

When they were first introduced, GasNets were demonstrated to be significantly more evolvable than a variety of standard ANNs on some noisy visually guided evolutionary robotics tasks (Husbands et al. 1998). Typically the increase in evolvability, in terms of number of fitness evaluations to a reliable good solution, was an order of magnitude or more. The solutions found were often very lean with few nodes and connections,

typically far fewer than were needed for other forms of ANN (Husbands et al. 1998, 2010). But the action of the modulatory gases imbued such networks with intricate dynamics: they could not be described as simple. Oscillatory subnetworks based on interacting “electrical” and “gas” feedback mechanisms acting on different timescales were found to be very easy to evolve and cropped up in many forms, from CPG circuits for locomotion (McHale and Husbands 2004) to noise filters and timing mechanisms for visual processing (Husbands et al. 1998; Smith et al. 2002). GasNets appeared to be particularly suited to noisy sensorimotor behaviors which could not be solved by simple reactive feedforward systems and to rhythmic behaviors.

Two extensions of the basic GasNet, the receptor and the plexus models, incorporated further influence from neuroscience (Philippides et al. 2005b). In the receptor model, modulation of a node is now a function of gas concentration and the quantity and type of receptors (if any) at the node. This allows a range of site-specific modulations within the same network. In the plexus model, inspired by a type of NO signaling seen in the mammalian cerebral cortex (Philippides et al. 2005a), as described earlier in this article, the emitted gas “cloud,” which now has a flat concentration, is no longer centered on the node controlling it but at a distance from it. Both these extended forms proved to be significantly more evolvable again than the basic GasNet. Other varieties include nonspatial GasNets where the diffusion process is replaced by explicit gas connections with complex dynamics (Vargas et al. 2007) and versions with other forms of modulation and diffusion (Husbands et al. 2010). In order to gain insight into the enhanced evolvability of GasNets, detailed comparative studies of these variants with each other, and with other forms of ANN, were performed using the robot task illustrated in Fig. 6 (Philippides et al. 2005b; Husbands et al. 2010).

Starting from an arbitrary position and orientation in a black-walled arena, a robot equipped with a forward-facing camera must navigate under extremely variable lighting conditions to one shape (a white triangle) while ignoring the

second shape (a white rectangle). The robot must successfully complete the task over a series of trials in which the relative position and size of the shapes varies. Both the robot control network and the robot sensor input morphology, i.e., the number and positions of the camera pixels used as input and how they were connected into the network, were under evolutionary control as illustrated in Fig. 6. Likewise, the network architecture (including number of nodes) and all properties of the nodes and connections and gas diffusion parameters were all set by the evolutionary search algorithm. Because of the noise and variation, and limited sensory capabilities (only very few pixels are used), this task is challenging, requiring robust, general solutions. The gantry robot shown in the figure was used. The evolutionary search algorithm employed a special validated simulation of the robot and its environment to calculate fitness (by measuring behavioral performance) (Husbands et al. 1998, 2010). Neural controllers evolved in this manner generate the same behavior when downloaded onto the real robot.

The comparative studies revealed that the rich dynamics and additional timescales introduced by

the gas played an important part in enhanced evolvability, but were not the whole story (Philippides et al. 2005b; Husbands et al. 2010). The particular form of modulation was also important; multiplicative or exponential modulation (in the form of changes to the transfer function) was found to be effective, but additive modulations were not. The former kind of modulations may well confer evolutionary advantages by allowing nodes to be sensitive to different ranges of input (internal and sensory) in different contexts. The spatial embedding of the networks also appears to play a role in producing the most effective coupling between the two distinct signaling processes (“electrical” and “chemical”). By exploiting a loose, flexible coupling between the two processes, it is possible to significantly reduce destructive interference between them, allowing one to be “tuned” against the other while searching for good solutions. It has been suggested that similar forces may be at play in spiking networks, where subthreshold and spiking dynamics interact with each other, which have been evolved to drive vision-based robot behaviors (Floreano et al. 2006, 2008). In the most successful varieties of GasNet, dynamics,

Nitric Oxide Neuromodulation, Fig. 6 *Left* The gantry robot. A CCD camera head moves at the end of a gantry arm allowing full 3D movement. In the study referred to in the text, 2D movement was used, equivalent to a wheeled robot with a fixed forward pointing camera. A validated simulation was used: controllers developed in the simulation work at least as well on the real robot. *Right*: The simulated arena and robot. The *bottom right* view shows the robot position in the arena with the triangle and rectangle. Fitness is evaluated on how close the robot approaches

the triangle. The *top right* view shows what the robot “sees,” along with the pixel positions selected by evolution for visual input. Only the values of these pixels from the camera image are fed into the neural network as visual input signals. All other pixel values are discarded. In this way the visual sensor morphology is effectively evolved. The *bottom left* view shows how the genetically determined pixels are connected into the control network whose gas levels are illustrated. The *top left* view shows current activity of nodes in the GasNet

modulation, and spatial embedding act in concert to produce highly evolvable degenerate (Tononi et al. 1999) networks.

Conclusions

Nitric oxide neuromodulation is an important example of a nonclassical neural signaling mechanism which reveals subtle new dimensions to the functioning of the nervous system. Simple connectionist point-to-point notions of information transfer are no longer valid: new understandings and new metaphors are needed.

Detailed models of neural processes incorporating diffusing chemicals are computationally very expensive and to date have been restricted to small numbers of neurons rather than whole behavior-generating neuronal circuits. Computational studies of NO neuromodulation in functioning circuits have therefore been of a more abstract nature and have resulted in new styles of ANN that have direct engineering applications. However, recent advances in parallel computing, including the advent of general purpose GPU computing, mean that we are about to enter an era where larger-scale detailed models will be feasible. This will allow important advances in understanding the functional roles of NO neuromodulation through the careful integration of computational and experimental studies of (biological) neural circuits operating under the influence of NO modulation.

N-Methyl-D-Aspartate (NMDA) Receptors, Conductance Models

Patrick D. Roberts

Department of Biomedical Engineering, Oregon Health and Science University, Portland, OR, USA

Definition

A glutamate receptor that is permeable to calcium ions and the current can be regulated by the postsynaptic membrane potential in addition to the binding of glutamate. NMDA receptors can act as coincidence detectors where presynaptic glutamate release combines with postsynaptic depolarization to pass calcium ions that initiate signaling pathways leading synaptic plasticity and other postsynaptic processes.

Detailed Description

NMDA receptors are named for the selective agonist (*N*-methyl-d-aspartate) that does not bind well

to other glutamate receptors. The receptor is non-selective to cations and can allow Na^+ , K^+ , and Ca^{2+} to cross the membrane. The permeability to Ca^{2+} renders this synaptic receptor important for initiating signaling cascades.

The channel can be blocked by extracellular magnesium ions that are released when the postsynaptic neuron depolarizes, greatly reducing the resistance of the pore to current flow. Because the receptor is voltage regulated, the NMDA current causes a depolarizing current and calcium ion injection when postsynaptic depolarization is coincident with presynaptic spikes.

Kinetics of NMDA Receptors

Mathematical representations of NMDA currents include the time-dependent synaptic conductance, $g_{\text{NMDA}}(t)$, and the voltage dependence of the current, $B(V)$.

$$I_{\text{NMDA}}(t) = g_{\text{NMDA}}(t)B(V)(V(t) - E_{\text{NMDA}}) \quad (1)$$

The time-dependent synaptic conductance represents the opening and closing kinetics of the receptor channels and may be based on a double exponential function (or a similarly shaped function).

$$g_s(t) = \bar{g}_s \left(e^{-t/\tau_1} - e^{-t/\tau_2} \right) \quad (2)$$

where τ_1 is the onset time constant ($\tau_1 < 2$ ms) and τ_2 is the decay time constant ($\tau_2 > 50$ ms) (Jahr and Stevens 1990). NMDA currents have a longer decay than AMPA currents (Jonas and Spruston 1994) and typically have a substantially smaller peak current.

The peak current is dependent on the postsynaptic membrane potential.

$$B(V) = \frac{1}{1 + ae^{-bV}c[Mg^{2+}]_o} \quad (3)$$

where $[Mg^{2+}]_o$ is the external magnesium concentration and the constants a , b , and c are derived empirically (Destexhe et al. 1998; Jahr and Stevens 1990) and typically $a = 0.33/\text{nM}$, $b = 0.06/\text{mV}$, and $[Mg^{2+}]_o \approx 1$ nM.

Computational Relevance

The importance of NMDA receptors for neural computation is twofold: (1) strengthen glutamatergic currents when a neuron is in an excited state and (2) initiate signaling cascades near the site of the synapse that lead to long-term changes.

Due to the long decay constant of NMDA receptors, the NMDA current can contribute significant depolarizing current to the postsynaptic neuron even though the peak current is much less than AMPA receptors. This is particularly true when the postsynaptic cell is in an excited state. NMDA receptors strengthen glutamatergic input in an excited state because the voltage dependency increases the current. This mechanism allows neurons to be controlled by a modulatory input so that their sensitivity to excitatory inputs is adjusted. The resulting responses can, for example, alter the sensitivity of sensory pathways in a nonlinear manner by descending inputs (Ossipov and Porreca 2006).

The ability of NMDA receptors to inject calcium ions into neurons when the timing of synaptic inputs is coincident with postsynaptic activity provides a mechanism for Hebbian synaptic learning (Collingridge and Bliss 1987). Many biological processes are sensitive to calcium signaling, and NMDA receptors provide an important calcium source for synaptic dynamics. If the signaling cascade leads to long-term potentiation of the synapse, then the participation of the presynaptic neuron in the excitation of the postsynaptic neuron leads to a strengthening of that particular synapse (Hebb 1949).

The amount and type of synaptic plasticity induced by NMDA receptors depend on the cell type and calcium influx. Examples of long-term potentiation (Collingridge and Bliss 1987) and long-term depression (Dudek and Bear 1993) have been found that depend on activation of NMDA receptors, but typically, potentiation requires a higher level of calcium influx than depression (Lisman 1989). Thus, the short-term dynamics of NMDA receptors are responsible for the long-term dynamics of the synaptic currents that affect the population dynamics of the neural circuitry.

Nomenclature of Ion Channels (IUPHAR Scheme)

David C. Sterratt

School of Informatics, University of Edinburgh, Edinburgh, UK

Synonyms

[Clone nomenclature](#)

Definition

The International Union of Basic and Clinical Pharmacology (IUPHAR) nomenclature of ion channels is an agreed standard for naming the voltage-gated and ligand-gated ion channels encoded in the genomes of human, mouse, and rat. The nomenclature is based on functional characteristics and structural protein motifs.

Detailed Description

Overview of Channel Naming

In rat, mouse, and human, there are over 140 channel subunits in the superfamily of voltage-gated-like ion channels and over 70 types of ligand-gated ion channel subunits. Typically, a subunit has many names, reflecting the history of its discovery and subsequent investigation. The IUPHAR Committee on Receptor Nomenclature and Drug Classification has worked to produce a unified nomenclature of the channel subtypes, which is designed to indicate the function of the ion channel. This scheme is also called clone nomenclature, as the properties of subunits are measured by heterologous expression of cloned receptors. Subunits can also be

referred to by gene nomenclature, i.e., the name of the gene that encodes the channel protein.

In the IUPHAR nomenclature, each name comprises a family identifier, followed by a type and, in some cases, a subtype. Overviews of the nomenclature for voltage-gated and ligand-gated subunits are given by Catterall and Gutman (2005) and Collingridge et al. (2009), respectively. Full details of the nomenclature are available from the official database of the IUPHAR Committee on Receptor Nomenclature and Drug Classification. For each subtype, this database has details such as other names for the channel, links to other databases of genes, drugs and proteins, associated proteins (including pore-forming subunits and auxiliary subunits), ion selectivity, voltage dependence, activators, tissue distribution, and physiological function. Many of the subtypes are expressed outside the brain.

There is also a more informal classification of the dynamics of currents arising from channels, for example, “delayed rectifier potassium current” or “T-type calcium current.” In the IUPHAR scheme these terms are used in the description of a channel type. The dynamics of ion channels depend not only on the primary subunits (which the IUPHAR scheme refers to) but also on the expression of auxiliary subunits, which cluster around the primary subunits that form the channel pore. This classification by ionic currents is used widely by electrophysiologists and modellers. Table 1 shows the relationship between the

current types, the clone nomenclature prefix, the human gene prefix, and the ionic current names (Sterratt et al. 2011).

The IUPHAR Scheme for Voltage-Gated Ion Channel Subunits

Ion Channels with a Principal Permeant Ion

The name of a channel that has a principal permeant ion contains the name of the ion, a letter to indicate whether the channel is principally gated by voltage or calcium, and then two numbers to indicate the type and subtype of the channel. For example, the T-type voltage-gated calcium channel is named Ca_v3.1, and the calcium-gated small/intermediate conductance potassium channel is named K_{Ca}3.1. There are some quirks in the system: for example, K_{Ca}4.2 is actually activated by sodium rather than calcium.

There are two families of potassium channel that are not strongly gated by voltage or calcium which have their own suffices: (i) Pairs of K_{2P} subunits with 2 P-loops form an entire channel, which has four P-loops. These channels give rise to leak currents in neurons. (ii) K_{ir} inwardly rectifying potassium channels open very quickly on hyperpolarization, depending on the extracellular potassium concentration.

There are also two families of calcium channel of less relevance to neuroscience. (i) CatSper channels were the first cation channel discovered

Nomenclature of Ion Channels (IUPHAR Scheme), Table 1 The relationship of ionic current types to the clone and gene nomenclatures

Current type	Official IUPHAR receptor prefix	Human gene prefix	Current names
Sodium	Na _v	SCN	I _{Na} , I _{NaP}
High-voltage-activated calcium	Ca _v 1, Ca _v 2	CACNA1	I _{CaL} , I _{CaN} , I _{CaR}
Low-voltage-activated calcium	Ca _v 3	CACNA1	I _{CaT}
Delayed rectifier and A-type potassium	K _v 2.2, K _v 3.2, K _v 1.4, K _v 3.4, K _v 4.1, K _v 4.2, ...	KCNA, KCNB, KCNC, KCND	I _{DR} , I _A
Calcium-dependent potassium	K _{Ca} 1, K _{Ca} 2	KCNMA, KCNN	I _C , I _{AHP}
Inward rectifier potassium	K _{ir}	KCNJ	I _{Kir}
Hyperpolarization-activated cyclic nucleotide gated	HCN1–4	HCN1–4	I _h

in sperm and are specific to sperm cells. (ii) TPC (two-pore channels) are cation ion channels related to the CatSper channels; TPC1 is found in kidney, liver and lung.

Nonspecific Ion Channels

There are three classes of channel in the IUPHAR scheme that are significantly permeable to more than one ion:

- CNG (cyclic nucleotide-gated family), activated by cyclic nucleotides such as cAMP and cGMP
- HCN (hyperpolarization-activated, cyclic nucleotide-gated family), activated in response to hyperpolarization
- TRP (transient-receptor potential family), gated by heat and second messengers

Chloride Channels

Chloride channels are not covered by the IUPHAR scheme.

IUPHAR Scheme for Ligand-Gated Ion Channel Subunits

The IUPHAR also has a scheme of naming 71 types of ligand-gated ion channel subunits, including the following: 5-HT₃ receptors, GABA_A receptors, glycine receptors, ionotropic glutamate receptor subunits, nicotinic acetylcholine receptors, P2X receptors, and ZAC. This scheme does not tend to be referred to in computational neuroscience studies.

[Noninvasive brain-machine interface](#)

Definition

A noninvasive *brain-computer interface* (BCI) is a device that allows users to send messages or

commands to devices, friends, family, or others through direct, noninvasive measures of brain activity.

Detailed Description

BCIs are communication and control systems that do not depend on the brain's normal output pathways such as peripheral nerves and muscles (Wolpaw et al. 2002). Hence, BCIs provide alternate methods to interact with the outside world not only for healthy people (Allison et al. 2007; Guger et al. 2009; Blankertz et al. 2010) but also for patients who cannot use their muscles but are cognitively intact (Nam et al. 2012; Sellers et al. 2010).

Noninvasive BCIs record information from sensors placed on or very close to the head. No surgery is required to implant recording devices, and noninvasive BCIs do not use any painful or hazardous methods. The most common BCI recording mechanism is the electroencephalogram (EEG), which uses electrodes placed on the surface of the head. These electrodes detect electrical changes in brain activity with millisecond resolution, thus providing insight into the timing and location of different mental activities. Electrodes are usually placed in an electrode cap, which allows fairly precise positioning of electrodes over distinct brain regions. Electrode caps and other electrode systems can fit in a purse or small bag. They are lightweight, relatively inexpensive, and easy to use. Most conventional electrodes require a small amount of electrode gel under each electrode to get a good connection between the scalp and each electrode.

Other noninvasive approaches have also been used in BCI research. A few BCIs have used magnetoencephalography (MEG), which records the brain's magnetic activity. These systems measure brain activity as quickly as EEG systems, although they measure a different type of activity. Functional magnetic resonance imaging (fMRI) and functional near-infrared spectroscopy (fNIRS) both measure changes in the brain's blood flow, rather than directly measuring electrical activity. The blood oxygenation

level-dependent (BOLD) signal reflects increased blood flow and oxygen consumption in brain areas that are active, such as motor areas involved in imagined movement. Blood flow changes take a few seconds to develop enough for reliable discrimination of brain states, which limits the speed of BCIs that rely on these methods. Also, fMRI systems (like MEGs) are neither affordable nor portable. Unless there are significant advances in these or other noninvasive neuroimaging approaches, EEG-based BCIs remain the most common means of noninvasive brain monitoring for BCIs.

Tasks in Noninvasive BCIs

In any BCI, a critical defining feature is the set of mental activities (and corresponding brain signals) that the BCI can detect. Many mental activities that might seem obvious control tasks for a noninvasive BCI – such as imagining an image, thinking of a specific word, or wishing to perform a goal – and do not elicit patterns of mental activity that can be reliably discriminated by noninvasive brain imaging methods. Thus, BCI developers have had to rely on mental activities that produce robust changes in the EEG or whatever method is used. Aside from producing distinct brain activity patterns, any mental activities in BCIs should be relatively easy for the subject to perform, quickly and repeatedly, and should ideally be relatively intuitive for the desired BCI application. For example, imagining left hand movement to move an avatar left or control a grasping device on the left hand seems like an intuitive, natural mapping between mental activity and output.

Most noninvasive BCIs rely on imagined movement or attention, and attention-based BCIs are typically divided into P300 BCIs and SSEP BCIs, described further below. The following subsections describe these three BCI approaches. Each section includes a figure drawn from a recent publication that depicts the electrode distribution and protocol from that study. The methods in these examples are not universal, but are typical of many BCIs that use that approach.

Motor Imagery BCIs

Many noninvasive (and invasive) BCIs record changes in neural activity associated with imagined movement. For example, a user might imagine moving the left hand, right hand, or foot. These activities each produce distinct patterns of event-related (de)synchronization, or ERD/S, over different sensorimotor regions. ERD/S typically entails changes in the frequency spectra around 8–14 Hz and sometimes beta harmonics of these frequencies. By analyzing these power spectra over different sites, a BCI can determine which movement the user imagined and thereby convey information from the user (Guger et al. 2003; McFarland et al. 2010; Vidaurre and Blankertz 2010). Motor imagery BCIs often rely heavily on central electrodes and surrounding sites, shown in Fig. 1b.

Motor imagery BCIs typically begin with a training period, which trains the user on the task and provides information about each user’s ideal frequencies and spatial regions that improves classifier performance. Motor imagery BCIs may entail longer training, lasting from several minutes to many sessions over months or years, to continue to improve performance (McFarland et al. 2010; Vidaurre and Blankertz 2010). Figure 1a shows the structure of a typical training session. Subjects are initially asked to look at a fixation cross on a monitor and may receive some cue (such as a tone). Next, an arrow points to a specific direction, indicating that the subject should perform corresponding motor imagery. For example, a left arrow might instruct the

subject to imagine moving the left hand. After the subject performs this imagery for several seconds, the trial ends, and there is a pause before the next trial.

Motor imagery BCIs often entail at least 5–10 min of training data to customize parameters for each subject. Online trials may use a similar trial structure, but present feedback throughout the motor imagery and/or at its end. A classical form of feedback has been a bar extending to the left or right; the direction indicates one of two movement directions, and the bar indicates the strength of the classification (Guger et al. 2003). Motor imagery BCIs have also provided feedback through many other applications and devices, such as spellers (Müller et al. 2008), orthoses (Do et al. 2013), and virtual environments (Leeb et al. 2007).

P300 BCIs

BCIs may rely on two types of attention-dependent EEG signals: P300s and steady-state evoked potentials (SSEPs). Each of these approaches relies on voluntary modulation of attention. When a user chooses to pay attention to a certain stimulus, thereby ignoring other stimuli, distinct patterns of EEG activity may be used to identify the target. Most attentional BCIs require a working visual system to produce distinct visual evoked potentials (VEPs), but have been validated with other stimuli as well.

When a person silently counts a certain stimulus (such as a flash or tone), the brain may produce

Noninvasive Brain-Computer Interfaces,
Fig. 1 Structure of a motor imagery study (Wang et al. 2012). The *left panel* shows one example of the structure of

each motor imagery trial. The *right panel* shows the electrode locations from that study

a series of transient event-related potentials (ERPs), including P300s, which are more robust than the ERPs elicited by ignored stimuli. ERPs are derived by isolating the time period after each flash (such as 800 ms) and measuring the voltage at each electrode site. These ERPs reflect attentional processing and updating of memory and context and can be elicited by visual, tactile, and auditory stimuli (Polich 2007). The P300 is most pronounced over parieto-occipital electrodes (Krusienski et al. 2008), and so P300 BCIs rely most heavily on posterior electrodes (see Fig. 2, right panel). Most P300 BCIs use a spelling application, in which different icons are presented on a computer monitor. These icons typically include letters, numbers, other characters, or commands (see Fig. 2, left and middle panels). The user is asked to focus on a specific character, called the target, and silently count each time the target flashes.

The flashing strategy has changed in recent years. Until recently, most P300 BCIs flashed characters by changing to color-reversed versions of the same character or flashing a solid color (Guger et al. 2009). However, recent work showed that the face-speller, in which characters change to a famous face, can elicit more robust ERP differences than a conventional P300 BCI and thereby improve performance (Kaufmann et al. 2011; Jin et al. 2012). Also, canonical P300 BCIs used the “row-column” flash approach, in which one row or column was highlighted in sequence (Farwell and Donchin 1988; Allison and Pineda 2003). One study found that a single character speller, which

flashed only one letter at a time, was inferior to the canonical row-column approach (Guger et al. 2009). More recent work found that “splotch” patterns that group characters in patterns that avoid rows and columns produce better results (Boccanfuso et al. 2005; Townsend et al. 2010; Jin et al. 2011).

Like motor imagery BCIs, P300 BCIs require a training period that usually lasts about five minutes. After that, the classifier is automatically updated with the best combination of electrode sites and weights for the different times after each flash. The P300 BCI is then ready for online use. About three target flashes are needed to produce sufficiently robust ERP differences for accurate classification. In a spelling application, the classified letter is normatively presented at the top of the monitor.

SSEP BCIs

Steady-state evoked potentials may also change based on voluntary attention, such as when subjects are asked to focus on a stimulus on one hand or one oscillating LED. Most BCI research involving steady-state potentials has used visual-based stimuli called steady-state visual evoked potentials (SSVEPs). The user may view a monitor with oscillating icons or a device with oscillating LEDs and focus on one of these visual targets. Occipital areas of the brain, over the primary visual cortex and nearby regions, will show an increase in the frequency of the oscillating stimulus and often harmonics as well (Allison et al.

Noninvasive Brain-Computer Interfaces,

using that matrix. The *right panel* shows electrode positions typical in P300 BCIs (Image from Guger et al. (2012b))

2010; Luo and Sullivan 2010; Panicker et al. 2011). Figure 2 presents one SSVEP study in which a user observed a box with four LEDs that each oscillated at a different frequency (10, 11, 12, or 13 Hz). By focusing on one of these frequencies, the user could convey one of four directional signals. About half of all subjects attained 100% accuracy, with about 35% more in the 90–100% accuracy range (Guger et al. 2012a). This approach has been used to control a mobile robot (Kapeller et al. 2013; Fig. 3).

While SSVEP BCIs have been widely validated, they would not work for users who cannot see. Steady-state auditory evoked potential (SSAEP) BCIs have been explored, but were less promising than ERP-based BCIs (Hill and Scholkopf 2012). Vibrotactile stimulation can elicit steady-state somatosensory evoked potential (SSSEP) activity at the eliciting stimulus frequency. Focusing attention on one of the frequencies (such as a vibrotactile stimulator on the left or right hand) increases power at the associated frequency, primarily over fronto-central electrode locations contralateral to the attended frequency. Thus, SSSEP BCIs rely on sensorimotor areas somewhat similar to motor imagery BCIs. SSSEP-based BCI systems allow users to communicate by focusing on a specific tactile stimulus

to convey information, such as designating the left hand for “yes” (Severens et al. 2013). The somatosensory system of behaviorally nonresponsive patients remains functional, even though their visual system is impaired.

Hybrid BCIs

Hybrid BCIs (abbreviated hBCIs) combine a BCI with another way that someone can convey information. An hBCI could combine a variety of input signals (shown in Fig. 4), such as:

1. Two same types of brain signals (e.g., EEGs)
2. Two different types of brain signals (e.g., EEG and near-infrared spectroscopy, NIRS)
3. One brain signal (e.g., EEG) and another physiological signal (heart rate or HR changes)
4. One brain signal (e.g., EEG) and another conventional input (e.g., eye tracker)

The first two systems may be classified as a “pure” hybrid, the third system as a “physiological” hybrid, and the fourth system as a “mixed” hBCI. Although hBCI research received little attention until recently, it has already gained significant attention (Pfurtscheller et al. 2010;

Noninvasive Brain-Computer Interfaces,
Fig. 3 Structure of an SSVEP BCI system. The *left panel* shows an electrode montage with a heavy emphasis

on occipital sites, which is common on SSVEP BCIs. The *right panel* shows the user observing the device with four LEDs (Image from Guger et al. (2012a))

Noninvasive Brain-Computer Interfaces, Fig. 4 Different types of hBCIs (From Pfurtscheller et al. 2010). Each panel presents a different way that a BCI may be combined with another input device

Allison et al. 2010, 2012; Müller-Putz et al. 2011; Choi and Jo 2013; Yin et al. 2013).

HBCIs may operate in a simultaneous and/or sequential manner. In a sequential BCI, the user controls one of the different input mechanisms at a time, rather than simultaneously. The sequential hBCI approach may use the output of one system as the input of the other system. For example, the first system could function as a “Selector” or “Brain Switch.” In some cases, the first BCI in a hybrid system simply turns the second BCI on or off. This approach has been validated with BCIs that combine ERD and SSVEP or SSVEP and P300 (Pfurtscheller et al. 2010; Panicker et al. 2011). A different approach to sequential hBCIs complements a BCI with another input system for other input for different goals. For example, one hBCI combines P300 and motor imagery BCIs to control a BCI mouse, select icons, or spell (Yu et al. 2013).

In a simultaneous hBCI, two input signals are processed at the same time. P300 and SSVEP measures have been combined to provide two signals to improve detection accuracy (Li et al. 2013; Allison et al. 2014). In these approaches, the user focuses on a target that both flashes and oscillates, thus eliciting both transient and steady-state attention-related changes. A different approach explored the combination of P300 and

SSSEP activity to improve accuracy (Severens et al. 2013). Some work has demonstrated simultaneous hBCIs that require users to perform different tasks simultaneously, essentially using two different BCIs at once, such as ERD-SSVEP (Allison et al. 2010) or P300-SSVEP (Panicker et al. 2011; Li et al. 2013). Hence, users might move a cursor in one direction with one BCI while simultaneously moving the cursor in another direction with another BCI. In Yao et al. (2013), users performed selective motor imagery while also focusing on a vibrotactile ring on one wrist. This hBCI approach improved accuracy. Choi and Jo (2013) combined multiple BCIs in a sequential and simultaneous fashion.

Therefore, different hBCIs have reduced disadvantages of the conventional “single” BCI system in different ways. They may provide a brain switch or enable a standby mode. HBCIs can increase accuracy and information transfer rate (ITR) by providing more selections, allowing control of more axes, or combining two signals to improve accuracy. A BCI might provide communication when the other system is not available, such as when the user is fatigued (Millan et al. 2010; Pfurtscheller et al. 2010; Allison et al. 2010, 2012; Müller-Putz et al. 2011).

This is not an exhaustive list of signals that could be used in noninvasive BCI systems. The

first BCI publication that showed a BCI helping a severely disabled patient relied on an EEG-based approach called slow cortical potentials (SCPs). A patient with late stage ALS learned to voluntarily produce slow changes in his SCP activity to move a cursor up or down, thereby controlling a spelling application (Birbaumer et al. 1999). However, this approach required months of training, did not allow rapid communication, and had a high illiteracy rate. Hence, SCP BCIs have received little attention of late. Other groups have developed BCIs based on spectral changes associated with the imagination of common mental tasks, such as writing, singing, performing math, or rotating an object (Millan and Mourino 2003; Sepulveda et al. 2007; Friedrich et al. 2012). These BCIs may be promising for some users, but also have not been as prominent as the three major noninvasive BCI approaches.

Feature Extraction and Translation

The success of a given BCI approach largely depends on effectively extracting relevant features from the brain signal measurements and translating these features into device commands. While many feature extraction and translation strategies have been explored for various types of BCIs, some commonly used approaches are summarized below.

Motor Imagery: Because motor imagery produces localized activity over the motor cortex, it is common to use a bipolar electrode reference or a Laplacian spatial filter centered over the region of interest, such as the right-hand region of the cortex. Likewise, since motor imagery produces changes in oscillatory activity in known frequency bands, measurements of the spectral amplitude or power in selected frequency bands are commonly used as features. One straightforward approach is to compute the bandpower of the EEG by bandpass filtering the EEG in the band of interest (e.g., μ or β) then squaring and smoothing the result. This gives a measurement of the temporal power fluctuations in the band of interest. Other spectrum estimation techniques such as Fast Fourier Transform (FFT)-based

methods and autoregressive (AR) models are commonly used to estimate the amplitude or power of the EEG within a band. Common spatial patterns (CSP) is another effective feature extraction approach that computes a set of optimal spatial filters for discriminating signal variance within a band.

With the spectral features extracted, for instance, modulation of the 12 Hz amplitude at Laplacian filtered C3, these features can be translated into continuous device control commands. While discrete classifiers can be used for translation, linear or nonlinear regression models such as ordinary least squares or support vector machine (SVM) regression can be advantageous in terms of user training and graded continuous control.

P300: Unlike motor imagery, the P300 and related ERPs are generally more broadly distributed spatially and the most useful features are time-domain amplitudes. For certain paradigms, such as the P300 speller, a generalized set of electrode locations is usually been defined for effectively capturing the response. The EEG is typically smoothed using a lowpass filter with a cutoff between 10 and 30 Hz and decimated by the corresponding factor to reduce the dimensionality. The ERPs are typically extracted within a 500–1000 ms poststimulus window. The resulting spatiotemporal amplitude features are then classified using a linear or nonlinear classifier such as stepwise linear discriminant analysis (SWLDA) or SVMs.

SSEPs: Because SSEPs are generally characterized by localized oscillatory activity, processing of these responses is very similar to motor imagery. For SSVEP, only electrodes overlying the occipital cortex are processed. Individual electrodes referenced to a frontal electrode can be effective, or spatial filtering methods such as CSP can be applied. Because SSVEP responses can occur at a sub-Hertz resolution over a comparatively wide band compared to motor imagery, FFT and AR methods are preferred over bandpower methods. The spectral features are then translated using any preferred classifier, which is typically multiclass. One of the most effective approaches for SSVEP is canonical correlation analysis (CCA), which computes

temporal correlations with reference sinusoids and an optimized spatial filter.

Major Challenges and Solutions

BCI Illiteracy

One of the persistent challenges in BCI research is finding a BCI that works for any user. BCI illiteracy occurs when a user is unable to attain effective control with a BCI (Allison et al. 2010; Kübler and Müller 2007; Pfurtscheller et al. 2010). This phenomenon may be more prominent in imagined movement BCIs, in which approximately 20% of users do not exhibit BCI performance adequate for effective control (Guger et al. 2003; Allison et al. 2013; Vidaurre and Blankertz 2010). Other work that explored universality with P300 and steady-state visual evoked potential (SSVEP) BCIs found that these approaches may work for a larger percentage of users, but not necessarily all of them (Allison et al. 2010; Guger et al. 2009, 2012a). Different methods to reduce illiteracy have been explored, such as improved training, proper instructions to users, and improved signal processing (Neuper et al. 2005; Leeb et al. 2007). However, even with these new techniques, some of the users still cannot use a resulting BCI system (Vidaurre and Blankertz 2010; Grosse-Wentrup and Schölkopf 2013).

BCIs that rely on endogenous signals (e.g., motor imagery-based BCIs) may not require visual stimulation to elicit evoked potentials but still require visual stimuli to provide instructions and feedback (Blankertz et al. 2010; McFarland et al. 2010). To provide BCIs for users with visual deficits, some researchers have turned to auditory or tactile stimuli to elicit necessary brain activity and provide feedback (Muller-Putz et al. 2012; Ortner et al. 2013).

Practical Field BCIs

Early BCIs recorded activity from users in shielded labs, with instructions to limit unnecessary movement, using fairly bulky equipment, with considerable expert help (Farwell and

Donchin 1988); (Wolpaw et al. 1991). Since then, there have been many efforts to validate BCIs outside of the lab, ideally with patient groups (Kübler et al. 2009; Sellers et al. 2010; Muller-Putz et al. 2012; Pineda et al. 2012; Ortner et al. 2013). A major challenge noted in extending BCIs to real-world use is robustness (Millan et al. 2010; Wilson et al. 2012; Allison et al. 2013; Schalk et al. 2012). BCIs should ideally work well at any time, in any location, with minimal equipment and assistance.

Improved signal processing and better electrode design have made EEG-based BCIs more robust to noise. Newer BCI amplifiers are much lighter and smaller than earlier designs. Wireless electrodes eliminate cables, which can generate noise, snag on equipment, and become tangled (Wilson et al. 2012). Newer BCIs rely on intelligent, self-adaptive software that can automatically customize many signal processing parameters to each user without help. Hence, the user gains improved accuracy (after a brief training session) without expert help. Some BCIs can detect when users are inattentive or producing no signal intended for BCI control, allowing for asynchronous operation and a standby mode (Muller-Putz et al. 2006; Sepulveda et al. 2007; Panicker et al. 2011). Intelligent software can also reduce errors through automatic error correction, effective feedback, and adapting to the environment (Millan et al. 2010; Allison et al. 2012; Wilson et al. 2012).

Until recently, each electrode required a small amount of electrode gel to attain good contact with the skin. The process of preparing each electrode for recording was somewhat messy and tedious and meant that EEG recording sessions (including for BCIs) typically required at least 20 min of preparation time. However, recent work from different groups has validated dry electrodes, which are more comfortable and require much less time to prepare. These electrodes can offer signal quality and BCI performance comparable to conventional gel electrodes (Lin et al. 2010; Zander et al. 2011; Chi et al. 2012; Guger et al. 2012b). These electrodes are often placed in a headband, headphones, or other head-mounted device. Wearable dry electrodes have also gained

attention among manufacturers developing BCI games for popular audiences, although these less expensive electrodes yield lower signal quality (Lin et al. 2010; Chi et al. 2012; Duvinage et al. 2013).

New Patient Groups

Some recent studies have shown that BCI technology may be useful for rehabilitation of different conditions – not just for communication and control. For example, BCI-assisted stroke therapy could better discern brain activity that predicts stroke therapy and recovery and inspire improved therapy using BCIs along with other techniques, such as robot-assisted therapy (Silvoni et al. 2011; Cincotti et al. 2012; Sarac et al. 2013; Teo and Chew 2014). Using a motor imagery BCI may also increase brain plasticity in motor areas and thus improve recovery from motor deficits resulting from stroke. Other work showed that BCI technology could help patients with other conditions, such as ADHD and autism (Pineda et al. 2012; Lim et al. 2012). These advances could make BCIs to a much wider group of patients.

Recent work has uncovered another patient group that may need BCIs. Depending on disease etiologies and varying degrees of brain damage, patients can have a range of conditions that are labeled as disorders of consciousness (DOC), including the vegetative state (VS) and the minimally conscious state (MCS), often including locked-in syndrome. DOC patients are diagnosed as “behaviorally nonresponsive” when they do not show any behavioral response to commands or repeated clinical examinations. Some patients diagnosed as behaviorally nonresponsive such as VS or MCS may in fact be conscious and able to communicate through a BCI. For example, some VS patients could modulate BOLD activity in the fMRI in response to instructions, such as thinking about playing tennis or moving in their homes (Owen et al. 2006). Three of 16 patients followed commands and performed specific motor imagery tasks (Cruse et al. 2011).

Very recent results showed that P300 and other BCIs may be able to both detect awareness and provide communication for some such patients. Some users did indeed exhibit differential ERP responses to autobiographical questions and could use the BCI to provide yes/no and even three-choice replies that could be used for communication. These people might otherwise remain unable to communicate and may remain misdiagnosed as permanently vegetative, affecting end-of-life decisions (Muller-Putz et al. 2012; Lule et al. 2013; Ortner et al. 2013, Risetti et al. 2013). There seems to be a particularly pressing need to help these patients, who seem to have an even greater need than others.

Conclusion

Noninvasive BCIs are communication systems that rely on direct, noninvasive measures of brain activity. Most noninvasive BCIs use one of the three types of EEG activity: ERD/s, P300 and related ERPs, and SSEPs. The first activity is usually elicited through imagined movement tasks, and the latter two categories usually involve visual attention. BCIs have been validated with a wide variety of patients and other end users and are becoming increasingly practical to a broader variety of people. Improved electrodes and amplifiers, wireless BCIs, better signal processing, hBCIs, reduced dependence on experts, wider field validation, and reduced cost, weight, and bulk (among other factors) are also making BCIs more useful and practical. New or existing companies may develop BCI products that appeal to a wider group of healthy users and further encourage smaller, cheaper, more convenient BCIs.

On the other hand, very few people use BCIs today. BCI illiteracy is a concern, particularly with patients in field settings. Most healthy users who use BCIs do so for fun or novelty, not for any practical benefit. Very few patients use BCIs, and most patients who do are supported by a local research group. Efforts to improve BCIs in various ways may help, and the next several years may see BCIs translate to new patient groups.

Definition

For the purpose of this chapter, numerical integration is defined as methods for the computation of approximate numerical solutions of initial value problems that involve the cable equation. This may seem a rather narrow focus, but the fact is that most computational models of biological neurons and networks include mathematical representations of the origin, propagation, and interaction of electrical signals. It has been noted that the deterministic diffusion of chemical signals is described by equations that are formally equivalent to those that govern the spread of electrical signals and are amenable to similar computational approaches (Carnevale and Hines 2006; Zador and Koch 1994). Readers who wish more detail on these and related topics are referred to Chap. 4 in Carnevale and Hines (2006), as well as Iserles (2008), Polyanin et al. (2008), and Wolfram Research (2013). Phenomena that involve small numbers of molecules or ions require methods that are beyond the scope of this chapter.

Detailed Description

The aim of this chapter is to provide an intuitive introduction to numerical integration in the context of simulating model neurons. It begins with a brief discussion of the nature of the equations that are to be solved, then examines some approaches that have been employed to solve them, and ends with some comments to help users apply numerical integration to their own models.

The Nature of the Problem

The spread of electrical signals along an unbranched neurite is governed by the one-dimensional cable equation, a partial differential equation (PDE) that is a statement of conservation of charge in an anatomically extended structure. The cable equation is often written as

$$\frac{\partial V}{\partial T} + F(V) = \frac{\partial^2 V}{\partial X^2} \quad (1)$$

where T and X are time and anatomical distance scaled by factors related to the physical size of a neurite and the electrical properties of its membrane and cytoplasm, and V and F are continuous functions of T and X (Rall 1977; Jack et al. 1983). Branched cellular architectures can be accommodated by combining multiple instances of the cable equation (one for each unbranched neurite) with appropriate boundary conditions. An analytical solution to the cable equation would express membrane potential as $v(t, x)$, a continuous function of time and position. In special cases it is possible to solve the cable equation analytically, and those solutions have produced many general insights into neuronal function (Rall 1977; Jack et al. 1983; Segev et al. 1995).

However, models that include the anatomical and biophysical complexities of real cells typically produce equations that do not have analytical solutions. The classical example is the Hodgkin-Huxley model of spike propagation along squid axon (Hodgkin and Huxley 1952):

$$C_m \frac{\partial v}{\partial t} + \bar{g}_{na} m^3 h (v - e_{na}) + \bar{g}_k n^4 (v - e_k) + g_l (v - e_l) = \frac{1}{4D} \frac{\partial}{\partial x} \left(\frac{D^2}{R_a} \frac{\partial v}{\partial x} \right) \quad (2)$$

In this equation, the gating variables h , m , and n are governed by first-order ordinary differential equations (ODEs) whose rate constants depend on local membrane potential v , and the parameters C_m , $\bar{g}_{na}$, $\bar{g}_k$, and g_l (specific membrane capacitance and channel conductance densities) may vary with position; furthermore, equations with such complexities must be solved numerically.

Discretization of the Cable Equation

A broad class of strategies for numerical solution of initial value PDEs is based on the notion of discretization. Discretization involves approximating a PDE, whose dependent variables are temporally and spatially continuous, with a set of difference equations that relate the dependent variables to each other at a finite set of points in time and space. This is done by approximating the temporal and spatial derivatives with algebraic difference formulas, and it produces a family of difference equations. The difference equations are then solved algebraically in order to compute the future values of state variables from their present (and possibly past) values. Instead of producing a solution that is a continuous function of time and position, the result is an approximate solution $v_{ij} = v(t_i, x_j)$ over a finite set of points in time and space. The error introduced by discretization depends on the algebraic formulas used to approximate the derivatives and the size of the temporal and spatial intervals between adjacent solution points.

Here we introduce basic concepts involved in discretization and then explore the stability and precision of various integration methods in the context of some simple models. This discussion is guided by the fact that models of neurons that involve biological anatomical and biophysical details pose a special challenge because the equations that describe them are very stiff, that is, they are characterized by a wide range of time constants. For example, even though neurons typically have membrane time constants on the order of tens of milliseconds, longitudinal redistribution of charge along the length of a neurite has sub-millisecond kinetics, and short neurites or dendritic spines can introduce sub-microsecond time constants. Single-compartment model neurons are not immune from stiffness, because some voltage- and ligand-gated ion channels (especially spike sodium channels and AMPAergic synaptic channels) have sub-millisecond time constants. Some voltage- and ligand-gated potassium channels are much slower, on the order of hundreds of milliseconds, while ion accumulation and active transport can produce concentration changes and shifts

of membrane potential that evolve over seconds or minutes.

Because of the stiffness of neural models, explicit integration methods (methods that predict future values from present and past values) can require impractically small Δt to avoid instability; this is illustrated below. Also, stability issues aside, the utility of high-order methods in fixed time step integration can be limited by the necessity of using short time steps to follow the time course of rapidly changing state variables. Consequently, only a few of the many methods that have been developed for numerical solution of PDEs are suitable for simulating models of biological neurons and networks.

Spatial Discretization

Spatial discretization is the first step in transforming the cable equation to algebraic difference equations. It approximates a spatially continuous physical system by a set of coupled compartments, each of which is small enough that membrane current density can be treated as nearly uniform over its surface. Figure 1 portrays such a region; as indicated by the arrows, axial currents i_a are reckoned as positive if they enter the region, and membrane current i_m is positive when it exits.

Numerical Integration Methods, Fig. 1 A compartment with approximately uniform membrane current density

Numerical Integration Methods, Fig. 2 Equivalent circuit of a discretized cable

If membrane current density varies widely over a model cell, many compartments will be needed to satisfactorily represent this variation. The ODE that describes membrane potential in the j th region is

$$C_{mj} \frac{dv_j}{dt} + i_{ion_j} = \sum_j \frac{V_k - V_j}{r_{jk}} \quad (3)$$

where the left-hand side is the sum of the capacitive and ionic membrane currents in the j th region and the right-hand side is the sum of the axial currents that enter this region from its immediate neighbors.

If the compartments are of equal size and the points at which membrane potential and currents are computed are located at the compartment centers, the right-hand side of Eq. 3 is the central difference approximation to the PDE's second spatial derivative

$$\frac{\partial^2 v}{\partial x^2} \approx \frac{v_{j+1} - 2v_j + v_{j-1}}{\Delta x^2} \quad (4)$$

where Δr is the resistance of the cytoplasm between adjacent compartment centers. Figure 2 shows the equivalent electrical circuit for three adjacent compartments along a neurite that has been discretized according to the central difference approximation.

Each compartment's membrane properties is depicted as the parallel combination of a capacitor and a box that represents the contribution of ion channels to transmembrane current. These are attached to a node in the middle of the compartment, at which membrane potential is to be calculated; each node is separated from adjacent nodes by cytoplasmic resistance.

The accuracy of the central difference approximation is $O(\Delta x^2)$, i.e., the local error introduced by replacing the second partial derivative in space with the central difference approximation is proportional to the square of the distance Δx between adjacent nodes (Iserles 2008). As a consequence, the central difference approximation leads to numerical solutions that can be treated as piecewise linear approximations to the real solution. In other words, if v_j and v_{j+1} are second-order accurate at adjacent nodes x_j and x_{j+1} , linear interpolation can be used to find an order accurate value v^* at any point x^* that lies between them.

The outcome of spatial discretization can be rearranged and written in vector form as

$$\frac{dy}{dt} = F(y, t) \quad (5)$$

where the elements of y include not only the membrane potentials in each compartment but also the state variables associated with other dynamic processes such as ion channel gating and concentrations of ions and second messengers. The right-hand side includes t to acknowledge the possible presence of time-varying parameters (e.g., synaptic conductances) or signal sources such as current or voltage clamps.

Temporal Discretization

Temporal discretization completes the transformation of a PDE to a set of algebraic equations by substituting an algebraic approximation for the temporal derivatives. There is a wide variety of temporal discretization schemes that are characterized by different degrees of stability and orders of accuracy. Those that are most relevant to computational neuroscience are discussed in section “Specific Integration Methods” below.

Specific Integration Methods

An ideal numerical integration method would generate highly accurate solutions quickly and robustly regardless of the details of the model. Unfortunately it is not possible to meet all these

goals simultaneously. In general, there is a tradeoff between speed, stability, and accuracy.

Explicit Euler

The explicit Euler method is conceptually the simplest and easiest to implement. This is a first-order accurate approach (local error is proportional to Δt) that predicts the solution at the next time t_{i+1} , from the values of the state variables and their derivatives at the current time t_i . It approximates the ODE of Eq. 5 with

$$y_{i+1} = y_i + F(y_i, t_i)\Delta t \quad (6)$$

so advancing a solution from one time to the next requires only calculation of the derivatives followed by some multiplications and additions.

However, the total computational cost of a simulation depends not only on how much effort is needed to advance from one step to the next but also on the number of advances that must be performed. Explicit Euler’s weakness is that Δt must be smaller than the smallest time constant in the system in order to ensure stable solutions that are free of spurious oscillations. For example, consider the ordinary differential equation (ODE)

$$\frac{dy}{dt} = -\frac{y}{\tau} \quad (7)$$

According to the explicit Euler method, given y_i at time t_i , the “recurrence equation” that generates y_{i+1} at time t_{i+1} is

$$y_{i+1} = y_i(1 - \Delta t/\tau) \quad (8)$$

The graphs in Fig. 3 compare the analytical solution for Eq. 7 with $\tau = 1$ and initial condition $y = 1$ (left panel, dashed line) to numerical solutions calculated by the explicit Euler method using different values of Δt . In both graphs the horizontal axis is time in seconds. If $\Delta t < \tau/2$ (left panel, solid line, $\Delta t = 0.5$), the numerical solution evolves smoothly with time and converges toward the analytical solution. Even though there is some error in the numerical solution, the solution is stable because the error decreases at each new time step and approaches 0 in the limit as $t \rightarrow \infty$.

If Δt lies in the interval $(\tau/2, t)$ (right panel, dashed line, $\Delta t = 1.9$), the numerical solution shows spurious oscillations. That said, it is still stable because error decreases with time and the solution converges toward the analytical solution. However, if $\Delta t > 2\tau$, the solution becomes unstable: each advance of the solution now amplifies whatever error was already present, so the oscillations grow without limit (right panel, solid line, $\Delta t = 2.1$).

The instability of the explicit Euler method is a particular problem for multicompartmental models because spatial discretization introduces very fast time constants, especially when very small compartments are present. Consider a model cell that has a 10 μm diameter spherical soma to which a cylindrical spine with diameter = length = 1 μm is attached. Let all membrane be passive with resting membrane potential 0 mV, specific membrane conductance and capacitance 0.001 S/cm² and 1 $\mu\text{F}/\text{cm}^2$, respectively, and cytoplasmic resistivity 160 Ωcm . The electrical equivalent circuit for this model is shown in Fig. 4, where the soma's parameters are $r_0 = 3.183\text{e}2$ meg Ω and $c_0 = 3.142\text{e}-3$ nF, the spine's parameters are $r_1 = 3.183\text{e}4$ meg Ω and $c_1 = 3.142\text{e}-5$ nF, and the coupling resistance between them is $r_a = 1.0186$ meg Ω . This circuit has two time constants: the slower one is 1 ms, and the faster is $\sim 3.2\text{e}-5$ ms.

If membrane potential is 1 mV in the soma and spine when $t = 0$, v_0 and v_1 should follow a monoexponential decay described by e^{-t} , i.e., membrane potential in the soma and the spine

should both decay toward 0 with a time constant of 1 (Fig. 5).

One might think that this model could be simulated using the explicit Euler method with $\Delta t = 0.1$ ms. However, the simulation blows up after 0.4 ms, as shown below. This happens because finite precision arithmetic introduces roundoff errors, which are magnified at each step until they completely dominate the simulation (Fig. 6).

Implicit Euler

Like explicit Euler, the implicit Euler method also has first-order accuracy. It differs from explicit Euler in that its recurrence equation is based on the derivative at the new time t_{i+1} , i.e.,

$$y_{i+1} = y_i + F(y_{i+1}, t_{i+1})\Delta t \quad (9)$$

Gathering all terms at time t_{i+1} to the left-hand side produces a set of algebraic equations

$$y_{i+1} - F(y_{i+1}, t_{i+1})\Delta t = y_i \quad (10)$$

which must be solved in order to compute the solution at the new time. Now we see why this is called the implicit Euler method: the new value of y is not computed directly from the previous value, but instead is implicit in a set of equations.

It is clear that implicit Euler requires more computations to advance from one step to the next than explicit Euler does. That said, solving Eq. 10 is easier than it might seem, because the rows on its left-hand side that correspond to the nodes of the

Numerical Integration Methods, Fig. 3 Left: given a small enough time step, the explicit Euler solution (solid line) is a stable approximation to the analytical solution of

Eq. 7 (dashed line). Right: oscillations and frank instability may result if the time step is too large. See text for details

Numerical Integration Methods, Fig. 4 Closely coupled compartments, such as those in this simple model, are a special problem for the explicit Euler method. See text for details

Numerical Integration Methods, Fig. 5 Analytical solution for the time course of membrane potential in the model of Fig. 4 if both compartments start at the same initial condition

Numerical Integration Methods, Fig. 6 The explicit Euler method is unstable even though the integration time step is small compared to the time constant that governs the decay of membrane potential in Fig. 5. See text for details

discretized cable equations are equivalent to a tri-diagonal matrix and can be solved very efficiently (Hines 1984), a consequence of the fact that neurons are singly connected branched structures.

Implicit Euler's extra computational effort is compensated by its greatly improved stability. Applying it to Eq. 7, temporal discretization yields

$$y_{i+1} + \frac{y_{i+1}}{\tau} \Delta t = y_i \quad (11)$$

so the recurrence equation is

$$y_{i+1} = \frac{y_i}{1 + \frac{\Delta t}{\tau}} \quad (12)$$

which is stable for any combination of positive τ and Δt , i.e., any plausible circumstance. Figure 7 illustrates numerical solutions generated from Eq. 12 for $\tau = 1$ and initial condition $y = 1$.

The analytical solution is plotted as a dashed line; the numerical solution in the left panel used a time step Δt of 0.5, and those in the right panel used Δt of 1, 2, and 5, respectively (thin, medium, and thick lines). Note that all numerical solutions converge on the analytical solution and that there are no spurious oscillations. Implicit Euler also handles stiff models very nicely; the two-compartment model described earlier poses no problem for it.

One useful feature of implicit Euler is that even when Δt is large compared to any time constant in a linear system, it still tends to produce solutions that are qualitatively correct; for a nonlinear system Δt must be small enough to capture important features of the solution trajectory (e.g., an action potential). For a stable linear system, a single-step approaches the steady-state solution as $\Delta t \rightarrow \infty$ (Chap. 4; Carnevale and Hines 2006).

Crank-Nicholson

The Crank-Nicholson (C-N) method applies the central difference approximation to both time and space, so it is second-order accurate in both (Crank and Nicholson 1947). C-N is conceptually equivalent to using implicit Euler to advance by $\Delta t/2$, then using explicit Euler to advance by another $\Delta t/2$, and involves little more effort than a single implicit Euler advance:

$$y_{i+1} = 2y * -y_i \quad (13)$$

Numerical Integration Methods,

Fig. 7 Numerical solutions to Eq. 7 that are generated with the implicit Euler method are stable even if the time step is large compared to the time constant

where y^* is the intermediate result produced by the implicit Euler half-step advance

$$y^* - F(y^*, t_i + \Delta t/2) \Delta t/2 = y_i \quad (14)$$

To understand why, consider this example that involves a single ODE. The implicit Euler half step is equivalent to starting at point $(t, y(t))$

$$(t, y(t)) \bullet$$

and moving to an intermediate point $(t + \Delta t/2, y^*)$ where the slope $F(t + \Delta t/2, y^*)$ points back to $(t, y(t))$.

$$\begin{array}{l} \bullet \\ \text{dy/dt} = F(t + \Delta t/2, y^*) \\ \bullet \\ (t + \Delta t/2, y^*) \end{array}$$

The explicit Euler half step then uses this same slope $F(t + \Delta t/2, y^*)$ to move from the intermediate point $(t + \Delta t/2, y^*)$ to the new solution point $(t + \Delta t, y(t + \Delta t))$.

$$\begin{array}{l} \bullet \\ \text{dy/dt} = F(t + \Delta t/2, y^*) \\ \bullet \\ \text{dy/dt} = F(t + \Delta t/2, y^*) \\ \bullet \\ (t + \Delta t, y(t + \Delta t)) \end{array}$$

Since the slope is the same for both half steps,

$$\begin{aligned} y(t + \Delta t) &= y(t) + 2(y^* - y(t)) \\ &= 2y^* - y(t) \end{aligned} \quad (15)$$

This result readily generalizes to a system described by a family of ODEs.

The advantages of C-N over first-order methods for dealing with time are that it offers greater accuracy for nearly the same computational effort when more accuracy is necessary and it allows use of larger Δt without sacrificing

accuracy when speed is important. Also, second-order accuracy in time means that linear interpolation produces second-order accurate values between adjacent solution times.

However, C-N is prone to spurious oscillations if the system equations are too stiff. This occurs if

$$\frac{\Delta t}{\tau_m} > \frac{2}{1 + 4\left(\frac{\lambda}{\Delta x}\right)^2} \approx \frac{1}{2} \left(\frac{\Delta x}{\lambda}\right)^2 \quad (16)$$

where τ_m is the membrane time constant, λ is the DC length constant, and Δx is compartment length – in other words, when the model's spatial discretization is too fine for the integration time step (Carnevale and Hines 2006). It can also happen if the model includes a voltage clamp, because voltage clamps introduce very fast time constants. Note that even if oscillations do occur, they die out with time, so C-N is stable.

Higher-Order Methods and Adaptive Integration

Methods that have a higher order of accuracy are tempting because of the possibility that the extra computational cost of using a high-order method will be repaid by the ability to take fewer, longer steps between simulation points without compromising simulation results. However, this advantage comes at the cost of greater computational burden per time step. Also, high-order methods tend to be unstable when applied to stiff equations unless Δt is kept small (Iserles 2008).

An alternative strategy for efficiently generating accurate simulations is to use an adaptive integration scheme, in which the computer

automatically adjusts integration step size and/or order of integration so that local error lies below a user-specified criterion. Adaptive integration can often reduce total run time, but the computational overhead per advance is larger than with fixed Δt methods and some simulations will actually slow down.

The principal advantage of adaptive integration is improved quality of the numerical results, since local error is controlled and solution points are calculated at shorter time intervals when state variables are changing rapidly and at longer intervals when not much is going on.

This is illustrated in the following figure, which shows an action potential generated by NEURON (Carnevale and Hines 2006) from a single-compartment model with $100 \mu\text{m}^2$ surface area and Hodgkin-Huxley membrane properties subjected to a $0.01 \text{ nA} \times 1 \text{ ms}$ stimulus current that started at $t = 1 \text{ ms}$. The simulation used the CVODES adaptive integrator of the SUNDIALS suite (Hindmarsh et al. 2005) with absolute error tolerance 0.001. The + marks on the voltage trace indicate the times at which solutions were generated; the other two graphs show how Δt and integration order were varied during the simulation in order to satisfy the error criterion. For most of the simulation, integration order was >2 and Δt was substantially longer than 0.025 ms, NEURON's default for fixed time step integration (dashed line in middle graph). Note that Δt became very small and order dropped back to 1 at the start and end of the stimulus current; this happened because an abrupt parameter change constitutes a new initial value problem and forces restart of the integrator (Fig. 8).

Practical Considerations

How to Select Δt and Δx

The general idea is to make Δt and Δx small enough that the simulation captures important features of model behavior in space and time with reasonable accuracy, but not so small as to needlessly prolong simulation time, increase storage requirements, or make results susceptible to cumulative roundoff error. Even if run time is not important, the tactic

Numerical Integration Methods, Fig. 8 Hodgkin-Huxley spike calculated by adaptive integration. *Top trace:* each solution point is marked by a +. *Middle and bottom traces:* integration time step and order vary to satisfy the error criterion

of cutting Δt and Δx in order to reduce the error from one time step to the next (“local error”) is eventually limited by the accumulation of local error, which increases global error.

That said, certain models and integration methods may limit one's options. As we have seen, the explicit Euler method becomes unstable if Δt is larger than the fastest time constant in the model, and avoidance of oscillations with the Crank-Nicholson method requires use of time steps small enough that temporal error does not outweigh spatial error (Eq. 16). Even with methods for which stability or oscillations are not an issue, it is important to remember that accuracy at short spatial scales may require the use of short time steps and vice versa (e.g., simulations of the time course of Ca^{++} concentration in the near vicinity of open channels). Often an empirical approach is necessary, such as making

Δt smaller until simulation results are qualitatively unchanged, then doing the same for Δx , and repeating until there is no further qualitative change in results.

Hines and Carnevale (2001) described various rules of thumb for spatial discretization of the cable equation and introduced a new approach called the “d_lambda rule” which bases spatial discretization on the AC length constant λ_f at a frequency f so high that membrane current is almost exclusively capacitive and ion channel density doesn’t matter. The rationale is that good temporal accuracy implies the accurate simulation of signal propagation at “high” frequencies. According to the d_lambda rule, a neurite is represented by N pieces of equal length where N is just large enough to satisfy

$$\frac{\text{Neurite length}}{N} < d_lambda \lambda_f \quad (17)$$

where the AC length constant for a cylinder with diameter d μm , cytoplasmic resistivity R_a Ω cm, and specific membrane capacitance C_m $\mu\text{F}/\text{cm}^2$ is

$$\lambda_f \approx \frac{1}{2} \sqrt{\frac{d}{\pi f R_a C_m}} \quad (18)$$

Membrane capacitive current far outweighs ionic currents at frequencies at least 5 times faster than the frequency that corresponds to the membrane time constant, i.e., $f > 5/(2 \pi \tau_m)$. For most cells, it turns out that 100 Hz is more than fast enough, and d_lambda = 0.1 at 100 Hz is sufficient to produce good results.

The advantages of the d_lambda rule include the facts that it is effective, avoids excessive discretization, and is easily automated. The NEURON Simulation Environment offers the d_lambda rule as a feature of its CellBuilder tool, but in principle it could be easily implemented for any multicompartmental simulator.

Physiological Precision

Any discussion of the accuracy of numerical integration in the context of empirically based

modeling in computational neuroscience would be incomplete without asking the question: how precise must a simulation be in order to be useful? The answer is it depends.

One concern often raised about empirically based models is the limited precision of experimental data. In order to be useful for simulation, such data are often fit to functions that may have a sound theoretical basis yet are only capable of approximating the actual relationships between dependent and independent variables. For parameters that result in a trajectory passing near a separatrix, simulation results may be highly sensitive to variation in any model parameter or simulation parameter (e.g., Δt , Δx , order of integration) (Chap. 4; Carnevale and Hines 2006); the same is true for the behavior of a system that lies near a bifurcation.

It is widely acknowledged that results that depend on very finely tuned parameters are biologically implausible because they seem unlikely to be robust.

But what degree of accuracy is justified by natural biological variability, let alone the quality of the data from which parameters are estimated? Golowasch et al. (2002) pointed out the wide range of parameter values observed in normally functioning neurons and provided evidence for covariance between parameters. To minimize the effects of biological variability and to avoid the confounding effects of parameter covariance, it would be best for all parameters to have been acquired in a single set of experiments on a single cell or network. However, this is not possible; modelers must rely on parameters gathered from experiments performed in different labs on different cell types from different species.

Seldom mentioned is another, deeper issue: the results of any model simulation are at least four times removed from the original physical system. The first separation occurs with the formulation of a conceptual model, which of necessity is a simplified representation of physical reality. Indeed, simplification affects all research, even that which does not involve computational modeling, because it is an unavoidable consequence of the way we develop an understanding of complex systems. Two more separations are imposed when the time and space derivatives are replaced

by discretization formulas; this produces a new system that is only an approximation to the original physical system. The fourth separation happens when the discretized equations are solved numerically. Each of these separations is a potential source of error that could reduce the value of a simulation as a means for gaining insight into the original physical system. Discretization schemes and numerical integration methods are useful to the extent that the errors they introduce are manageable and allow at least a qualitative understanding of the original conceptual model.

To summarize, numerical integration applied to computational neuroscience models computes an approximate solution to one or more equations that are themselves approximations, and everything rests on partial knowledge inferred from imprecise measurements. In light of this, judgment is required when applying numerical methods so that results have what might be called “physiologically appropriate precision.”

Oculomotor Control, Models of

Adonis K. Moschovakis

Department of Basic Sciences, Faculty of Medicine, University of Crete and Institute of Applied and Computational Mathematics, Heraklion, Greece

Definition

A system of differential equations simulating the part of the brain that is responsible for the control of ocular movements. Each equation describes the evolution of the output of one unit (which can be a single neuron, a group of similar neurons, or the aggregate operation of a nucleus or brain area) given the inputs it receives and its intrinsic properties.

Detailed Description

The oculomotor system is one of the best understood parts of the mammalian brain. It is made up of more than 50 different classes of cells occupying several areas and nuclei distributed through much of the brain of higher mammals. Computer models allow us to organize the mass of available information about this system, to determine whether existing knowledge is sufficient to account for its overall properties as well as of the

cells that comprise it, and to derive precise quantitative predictions in order to guide future research. Models are validated against experimental evidence, in that (1) model output should fit oculomotor psychophysics, (2) the activation functions of model units should fit known neurophysiology, (3) connections between model units should fit known neuroanatomy, and (4) “lesion”/“activation” of model units should fit neurology and the results of lesion, ablation, reversible inactivation, and central microstimulation studies. Ideally, model assumptions and predictions are consistent with all four classes of experimental data, *simultaneously*. However, reliance on unknown connections, discharge patterns, and the generation of unheard of motor responses is sometimes valuable as it can lead to the design of experiments to see if they reflect reality, and the “discovery” of previously unseen or disregarded entities (cells, anatomical connections, or patterns of eye movements).

There are five different kinds of eye movements each controlled, largely independently, by one of the five different oculomotor subsystems. Modeling efforts generally target one of these subsystems and, accordingly, I will describe them separately. Figure 1 provides examples of these movements, recorded from primates ((a) rapid eye movements, saccades; (b) vestibuloocular responses, VOR; (c) optokinetic responses, OKR; (d) smooth pursuit; (e) vergence/divergence) together with block diagrammatic illustrations of the subsystems responsible for

Oculomotor Control, Models of, Fig. 1 The different types of eye movements executed by monkeys and the subsystems that serve their execution (Modified from a previous publication of the author, 2009). (a) Saccades. (b) VOR. (c) OKR. (d) Smooth pursuit. (e) Vergence. Note

their execution. All five oculomotor subsystems feed into the final common path, the motoneurons (MNs), which innervate one of the six extraocular muscles in each eye.

To generate an eye movement, the signals carried by OMNs must fit the mechanics of the eye, the surrounding orbital tissue and contracting/relaxing muscles (collectively referred to as the oculomotor plant). Knowledge of the dynamics of the plant allows one to calculate the signals needed to drive it. Accordingly, considerable modeling and experimental effort has been invested in elucidating these. If the transfer function of the oculomotor plant (the Laplace transform of its impulse response) were a single pole low-pass filter (this is what is assumed with the use of the expression $1/[sT_e + 1]$, T_e being its time constant), it would need pulse-step increments in force to produce a saccade (Robinson 1981a). The assumption that the transfer function of the

oculomotor plant has additional poles and zeroes (the roots of its denominator and numerator polynomials, respectively) leads one to expect more complex control signals (Goldstein 1987; Sklavos et al. 2005).

Models of the Saccadic System

Saccades are the rapid eye movements with which humans and other primates explore the visible world. Figure 1a includes a minimalist illustration of the neural subsystem entrusted with their control. Its central unit is the BG (burst generator). This is a fairly complex circuit (Moschovakis et al. 1996) made of several classes of neurons and is often modeled in its own right (e.g., Scudder 1988; Moschovakis 1994). The BG compares desired gaze displacement (desired gaze direction according to others) with actual gaze

displacement (direction). It uses a frequency code to specify the size of saccades (in that the frequency of discharge of its cells increases with the size of the movement) in a Cartesian frame of reference (in that a leftward horizontal BG is responsible for leftward horizontal saccades, an upward BG is responsible for upward saccades while additional burst generators deal with rightward and downward movements). Because the signals compared are entirely confined to the central nervous system, the control loop concerned is known as a “local loop.”

The BG sends signals to motoneurons both directly and indirectly through a neural integrator (NI). This is also a fairly complex piece of neuronal machinery (Moschovakis 1997) that is also modeled separately (Sklavos and Moschovakis 2002). Its transfer function, $T_i/(sT_i + 1)$, has a time constant (T_i) very long relative to that of the eye (more than two orders of magnitude longer). Together the BG and the NI match the command signals to the mechanical properties of the eye (collectively acting as the inverse model of later literature in a process known as impedance matching). In addition signals exiting the BG and the NI must respect eye conjugacy (the fact that during saccades, smooth pursuit, etc., the eyes move in the same direction and by roughly the same distance) and ensure the implementation of Hering’s law of equal innervation. Finally, neural machinery must be deployed to ensure the implementation of Descartes’ rule (i.e., that antagonist muscles will be inactivated when synergists are activated) and to couple orthogonal burst generators (as in the case of oblique saccades).

The box labeled SC stands for the superior colliculus, also a piece of circuitry that has been extensively modeled (e.g., Waitzman et al. 1991; Arai et al. 1994; Bozis and Moschovakis 1998). It serves as the model’s sensorimotor interface and ensures the accuracy of the movement relative to the location of the target that elicits it. The SC is a layered midbrain structure that uses polar coordinates to represent retinal error ((e) the distance between the fovea and the retinal representation of visual targets) in terms of the rostrocaudal and mediolateral location of active neurons in a sheet of similar cells comprising its superficial layers: targets near the fovea are represented rostrally and

peripheral targets caudally while medial (lateral) sites represent upper (lower) targets. A similar place code is employed in its deeper layers to represent movement metrics which contrasts the frequency code that motor-related brain structures usually employ for this purpose.

Models of the VOR

Figure 1b contains a simplified illustration of the three-neuron arc that serves the vestibuloocular response (Robinson 1981b). Disregarding the adaptation of the peripheral end organ, its lumped transfer function relates eye velocity in the head $\dot{E}$ to head velocity in space $\dot{H}$ and in Laplace transform notation is $\frac{\dot{E}(s)}{\dot{H}(s)} = -g \frac{sT_{vor}}{sT_{vor} + 1}$. Its gain, g (the negative sign indicates that the eye moves in a direction opposite to that of the head), is close to 1 and is under cerebellar adaptive control to compensate for modifications of the biology that accrue with the passage of time (e.g., the power of the glasses that the subject wears). The lumped transfer function of the VOR is the product of the transfer functions of all units between the end organ that senses head movement and the eye. The left-hand unit stands for the former (T_c being the time constant of the cupula). The difference between T_c (about 5 s) and T_{vor} (about 15 s; Robinson (1981b)) must be due to some other signal reaching the secondary vestibular neurons (VN; the $\dot{H}_{oA}$ signal considered below). The VN signal is sent to extraocular motoneurons, either directly or through a neural integrator (marked $T_n/(sT_n + 1)$) similar to that of the saccadic system. The simple circuitry of Fig. 1b provides an adequate account of the generation of the slow phases of vestibular nystagmus. The additional machinery needed to generate the quick phases (marked with asterisks) may involve additional classes of saccade-related neurons (Kitama et al. 1995) and has been the object of modeling efforts dedicated to it (Chun and Robinson 1978).

Models of the OKR

Because the transfer function of the canals (the leftmost unit of Fig. 1b) is $\frac{\dot{H}_c}{\dot{H}} = \frac{sT_c}{sT_c + 1}$, the VOR

compensates head velocity by only 37% 4 s ($= T_c$) after the onset of head movement and by less than 5% after 12 s. The optokinetic subsystem was developed to address this lack of sustained (i.e., low frequency) responses of the vestibular system to head movements. Figure 1c adds a block diagrammatic illustration of this second, optokinetic, subsystem onto the vestibular one and emphasizes the fact that the two subsystems cooperate closely. The summing junction on the right stands for the vestibular nuclei (VN) which receive both a transient estimate of head velocity from the vestibular end organ ($\dot{H}_c$) and the optokinetic signal ($\dot{H}_{ok}$) from the positive feedback loop on the left. The latter combines an efference copy of the eye velocity command sent to the plant ($\dot{E}'$) with retinal slip velocity ($\bar{e}$) to estimate the velocity of the movement of the visual world relative to the head ($\dot{W}_h = -\dot{H}_v$), the visual system's estimate of head velocity (on the leftmost summing junction, tentatively identified as the NRTP, the nucleus reticularis tegmenti pontis). The high-frequency components of this signal are removed by the low-pass unit $1/(sT_o + 1)$ to avoid duplication of the high-frequency range of the vestibular signal. The gain of its forward path, $\dot{H}_{ok}/\dot{e}$, is $-G_{ok}/(sT_{okan} + 1)$, where $G_{ok} (= 1/1 - k)$ is about 3–5 if eye velocity is 70–80% of drum velocity, and Tokan is the time constant of the optokinetic after-nystagmus (measured by rotating a drum at a constant velocity around the subject to drive the system to a steady state and then turning the lights off to open the outer, non-illustrated feedback loop that minimizes retinal slip velocity). The additional machinery needed to generate the quick phases of the optokinetic nystagmus (marked with asterisks in Fig. 1c) has also been the object of modeling efforts (e.g., Anastasio 1997).

Models of the Smooth Pursuit System

This phylogenetically most recent oculomotor subsystem is poorly developed in cats but evolved in foveate animals such as primates (Eckmiller

1987). Unlike afoveate stabilization of retinal images accomplished by the VOR and OKR, pursuit can stabilize images on a miniscule part of the retina while ignoring retinal slip everywhere else (Robinson 1981a). As with the OKR, relatively recent models of pursuit (e.g., Lisberger et al. 1987) also use a positive feedback loop such as that shown in Fig. 1d (modified from Robinson et al. 1986). Additional important features include the emphasis on the reconstruction of target velocity ($\dot{T}'$) from desired eye velocity ($\dot{E}'$) and retinal slip velocity ($\dot{e}$) and use of a delay (τ) on the forward limb of the feedback loop and of a model of the short plant lag ($1/sT_{e2} + 1$) on its return limb. The fact that smooth pursuit normally starts with a saccade provides one more example of the close cooperation between distinct oculomotor subsystems.

Models of Disjunctive Eye Movements (Vergence/Divergence)

To look between distant and close targets, the eyes must be moved disjunctively, i.e., in different directions, the right eye to the left and the left eye to the right in the example shown in Fig. 1e. The resulting change of the angle between the two lines of sight (vergence angle, v) is slow, largely dominated by the dynamics of the plant. The time course of v is almost exponential (with a time constant roughly equal to 0.2 s) in response to a sudden change of retinal disparity (a steplike jump of the target from far to near). Figure 1e illustrates an early model of the vergence system that emphasizes their time course (Robinson 1981a). It includes a delay (τ) of about 160 ms (the unit marked $e^{-s\tau}$), the experimentally determined latency of the system's response, and the notion that central pathways convey to extraocular movers a signal proportional to retinal disparity and five times its time integral. More recent models of the vergence system emphasize its interaction with the much faster saccadic system in a manner that allows for surprisingly quick changes of vergence angle.

Olfactory Computation and Adult Neurogenesis

Hermann Riecke

Department of Engineering Sciences and Applied Mathematics, Northwestern University, Evanston, IL, USA

Definition

The initial processing of olfactory information (“olfactory computation”) by the brain is performed in the olfactory bulb. Strikingly, even in adult animals the largest population of neurons

in this network is undergoing persistent turnover through neurogenesis and apoptosis, i.e., through the addition of new neurons and the subsequent death of a large fraction of them. This endows the network with computational power that yet has to be fully explored.

Detailed Description

Anatomy of the Olfactory Bulb

Olfactory processing begins with millions of olfactory receptor neurons (ORN) in the nasal epithelium. Each ORN expresses exactly one receptor gene, which determines the ORN's sensitivity spectrum across all odors. The number of different active receptor genes ranges from 50 in drosophila and 350 in humans to over 1000 in mice and rats (Murthy 2011). All ORNs expressing a given receptor gene project to a small number of glomeruli in the outermost layer of the olfactory bulb. Taken together, the inputs to all the glomeruli form an activation pattern or "olfactory image" that constitutes the first representation of an odor in the olfactory bulb. An initial reshaping of these patterns is performed in the glomeruli through intra- and inter-glomerular inhibition involving various types of periglomerular cells, external tufted cells, and short-axon cells (Fig. 1). Each glomerulus drives multiple mitral and tufted cells, which represent the principal cells of the olfactory bulb and project to various cortical regions.

A second reshaping of the odor representation arises from the mutual inhibition of mitral/tufted cells via granule cells, which constitute the largest population of neurons in the olfactory bulb. This inhibition is mediated by reciprocal dendrodendritic connections between mitral/tufted cells and granule cells on the secondary dendrites of the mitral/tufted cells. Since these dendrites can span across large fractions of the olfactory bulb, this inhibition can be long range. The reciprocal connections are comprised of glutamatergic, excitatory synapses from the mitral/tufted cells to the granule cells that are colocalized with GABAergic, inhibitory synapses from the granule cells back onto the

Olfactory Computation and Adult Neurogenesis, Fig. 1 Major cell types of the olfactory bulb and some of their connections with the cortex. The glomeruli (*glom*) are comprised of an ensemble of external tufted (*green*), periglomerular (*red*), and short-axon cells (*purple*). New adult-born periglomerular and granule cells arrive from the subventricular zone (*SVZ*). Excitatory (inhibitory) synapses are marked by *triangles* (*bars*)

respective mitral/tufted cells. The granule cells also receive centrifugal excitatory input from cortical structures like piriform cortex.

Physiology of Adult Neurogenesis

The olfactory bulb and the dentate gyrus are the only major brain areas in mammals to which new neurons are added in a steady stream even in adult animals. This has been best studied in rodents where on the order of 30,000, new interneurons arrive in the olfactory bulb every day (Kelsch et al. 2010). The vast majority of them develops into granule cells and a small fraction into periglomerular cells. Both cell types integrate functionally into the already established circuitry of the olfactory bulb. While a large fraction of the new neurons survives only for a brief period of 2–3 weeks, some new neurons survive for many months.

Adult-born periglomerular cells and granule cells differ in various aspects of their development (Lepousez et al. 2013). Periglomerular cells develop the ability to spike before their excitatory synaptic contacts appear and there is no strict order in which glutamatergic and GABAergic synapses are established (Kelsch et al. 2010). In contrast, in granule cells GABAergic inputs arise before glutamatergic ones, and the sodium currents that underlie action potentials develop only after synapses receiving excitatory inputs are formed. Moreover, the proximal synapses representing excitatory inputs from mitral cell axon collaterals and from cortical structures develop before the distal reciprocal synapses with mitral cells (Kelsch et al. 2010).

Even after their integration into the bulbar circuit, the adult-born cells undergo further development. Young adult-born periglomerular cells are more excitable than mature ones; this may also hold for granule cells (Lepousez et al. 2013). Proximal synapses of granule cells can undergo significant long-term potentiation, but only while the cells are young (Kelsch et al. 2010). Structurally, however, even in mature adult-born granule and periglomerular cells, the synapses exhibit substantial turnover, which is reduced in response to enriched odor exposure (Livneh and Mizrahi 2012).

The most striking feature of periglomerular cells and granule cells is the precise regulation of their survival and death. Their survival probability strongly depends on environmental factors. Odor enrichment during a critical period enhances their survival, while odor deprivation reduces it. In granule cells the critical period lasts from about 14 to 28 days after they are born (Lazarini and Lledo 2011); it begins therefore before the granule cells' distal synapses with the mitral cells are developed. The survival of periglomerular cells is sensitive to enrichment at least for 6 weeks. The detailed mechanisms controlling the survival are not yet understood. It is clear, however, that the apoptosis is the result of a precisely regulated program that removes the cells predominantly during postprandial slow-wave sleep (Lepousez and Lledo 2011). On the cell level, survival is enhanced if the excitability of granule cells is

increased by genetic means and vice versa (Kelsch et al. 2010).

Impact of Adult Neurogenesis on Behavior

Adult neurogenesis has substantial impact on the ability of animals to discriminate similar odors and to retain odor memories. Spontaneous odor discrimination is often assessed using a habituation task that makes use of the fact that animals lose interest in an odor that is presented repeatedly. If after habituation to an odor an animal explores a new odor significantly longer, it is clear that it is able to discriminate between the two odors. It has been found that mice can learn to discriminate spontaneously between very similar test odors if they are presented repeatedly over the course of 5–10 days with odors that are related to the test odors. This perceptual learning is compromised if adult neurogenesis is suppressed (Lazarini and Lledo, 2011).

Adult neurogenesis plays also a role in memory. In the habituation task, mice with intact neurogenesis remember an odor after a single exposure for at least 120 min. With adult neurogenesis suppressed, however, they treat a repeated odor as a novel odor after as little as 60 min. Similarly, in a long-term memory task in which mice have to retrieve a reward from one of the two odorized holes, intact animals remember the correct odor association for 5 days, while animals without neurogenesis do not. Interestingly, even though animals with and without functional neurogenesis do not remember an odor any more after 30 days, the intact animals relearn the previously memorized odor faster than those with suppressed neurogenesis (Sultan et al. 2010). It is important to note that this enhancement of long-term memory through neurogenesis is only found when the animals are trained on an operant task, i.e., if the animals actively have to associate an odor with a decision. Tasks in which the relevant odor is only passively associated with a reward do not enhance neurogenesis and their memory is not compromised when neurogenesis is suppressed (Lazarini and Lledo 2011).

Computational Modeling

So far, adult neurogenesis in the olfactory bulb has been studied from a modeling perspective only to a limited extent. Motivated by the general notion of the importance of contrast enhancement in early sensory processing and by the observation that in zebra fish the olfactory bulb reshapes odor representations such that the correlation between the activity patterns representing similar odors is reduced (Friedrich and Laurent 2001), the focus has been on the decorrelating function of the olfactory bulb.

Due to the high dimension of odor space, the two-dimensional activity patterns evoked by odor stimuli in the input layer of the olfactory bulb are fractured. Thus, in contrast to the stimuli of the visual, auditory, and somatosensory system, these patterns are not characterized by a smooth map. Instead, the chemical response spectra of neighboring glomeruli are not much more similar than those of glomeruli that are far apart (Murthy 2011). A neuronal network that has to process such complex activation patterns is quite likely to reflect that complexity. Surprisingly, sparse random networks of thresholding neurons quite effectively decorrelate such patterns (Wiechert et al. 2010).

At the same time, it has been pointed out that many odors do not have an inherent meaning to animals and that the interpretation of these odors is learned by experience (Wilson and Stevenson 2006). This suggests that the olfactory networks adapt to their odor environment. From this perspective it is natural to assume that one role of the turnover of interneurons in the olfactory bulb is to restructure the network and to enable it to adapt to the demands of the animal's environment. Such processes could generate networks that reflect the complexity of the representations of the relevant odorants.

In an early adaptive computational model, the effective mutual inhibition between pairs of mitral cells was taken to depend on the product of their activities, averaged across an odor ensemble (Cecchi et al. 2001). This simple evolution of the effective inhibition was sufficient to allow the network to learn to decorrelate the stimuli. In

later work the granule cells were modeled explicitly with a steady stream of new cells connecting to randomly chosen mitral cells through reciprocal synapses (Chow et al. 2012). It was found that if the cells' survival required that their activity across an odor ensemble surpass a threshold, such networks learn to decorrelate even very similar stimuli. This process could underlie the neurogenesis-dependent perceptual learning observed experimentally. As had been found experimentally, new granule cells were found to be more likely to respond to novel odors in this model. The decorrelation achieved by this network can be understood to arise in part from a normalization in which the activities of different mitral cells – averaged across the odor ensemble – are evened out.

Possible consequences of the experimentally observed enhanced excitability and plasticity of young adult-born interneurons have not yet been explored theoretically.

Conclusion

Adult neurogenesis represents a fascinating aspect of olfactory computation. It plays an important role in the processes underlying odor discrimination and memory. Modeling has so far only elucidated its possible role in odor decorrelation, which may contribute to odor discrimination. Since the granule cells involved in the neurogenetic turnover receive substantial direct glutamatergic input from cortical areas, it seems likely that adult neurogenesis plays a much more refined role in odor processing than is apparent in experiments so far. What this role might be is yet unknown.

Olfactory Computation in Antennal Lobe and Mushroom Bodies

Maxim Bazhenov¹ and Mark Stopfer²

¹Department of Cell Biology and Neuroscience, University of California, Riverside, CA, USA

²National Institutes of Health, NICHD, Bethesda, MD, USA

Definition

The olfactory system maps complex and high dimensional stimuli (odors) into unique and reproducible dynamic ensembles of neuronal activity. In the insect, olfactory receptor neurons (ORNs) synapse onto a smaller group of excitatory projection neurons (PNs) and inhibitory local neurons (LNs) in the antennal lobe (AL) (Fig. 1). The odor information is then transferred to the mushroom body (MB), a structure

analogous to the olfactory cortex and where olfactory memories are formed. Inhibitory circuits of the AL and the MB shape the odor representation as it progresses through the olfactory system. The insect system is advantageous for studying and modeling olfactory coding because it is relatively simple and amenable to genetic manipulation.

Detailed Description

Olfactory neurons respond to static stimuli with oscillatory and temporally structured responses. The presence of odor-elicited oscillations in the olfactory systems of many animals including insects suggests oscillatory neural synchrony may play a fundamental role in odor encoding. Indeed, when the 20 Hz oscillations were specifically blocking by locally injecting picrotoxin into the antennal lobe (AL), locust olfactory neurons in a brain area called the beta lobe underwent a breakdown in the specificity of odor responses (MacLeod et al. 1998), and honeybees, in a behavioral test, lost the ability to discriminate odors (Stopfer et al. 1997). These results demonstrate oscillatory synchronization of AL neurons is needed for fine odor discrimination.

Computational models helped reveal mechanisms of synchronized network oscillations. Spikes in excitatory cells trigger spikes in widely-branching postsynaptic inhibitory neurons, whose spikes, in turn, produce inhibitory potentials in excitatory cells. This inhibition systematically delays and synchronizes the generation of the next excitatory response, thereby creating widespread network oscillatory synchrony (Borgers and Kopell 2003). A model of spike synchronization in the honeybee AL, also dependent on local inhibition, has been proposed to explain the experimentally-observed impairment of sensory discrimination when inhibition is blocked (Linster and Cleland 2001).

Interestingly, AL oscillations are generally not evoked by the first presentation of an odorant. Oscillations, rather, emerge gradually over the course of multiple encounters with a given odorant, provided the encounters occur close together in time. Electrophysiological (Stopfer and

Olfactory Computation in Antennal Lobe and Mushroom Bodies, Fig. 1 Information flow in the insect olfactory system. Olfactory receptor (OR) neurons in the antenna provide simply-structured input to the antennal lobe (AL). There, projection neurons (PNs) and local neurons (LNs) interact in part through feedback inhibition (*f.b.i*) to transiently synchronize spiking, and to generate

complex temporal firing patterns in PNs. PNs then provide distributed and temporally structured output to the Mushroom body (MB) and lateral horn (LH). In the MB, intrinsic neurons called Kenyon cells (KCs) interact through feedback inhibition with the unique Giant Gabaergic Neuron (GGN), resulting in very sparse and specific firing in KCs. GGN also provides feedforward inhibition (*f.f.i*) to the LH

Laurent 1999) and computational (Bazhenov et al. 2005) evidence suggests the increase in oscillatory synchronization results from activity-dependent plasticity within the AL. Models indicate that this plasticity, when engaged by repeating odor stimuli (as often occurs in nature) achieves robust stability against noise.

In the locust, GABA_A-dependent synchronization of a given pair of PNs is generally transient. Usually, after a few hundred milliseconds of firing spikes that are phase-locked to the oscillations, the synchrony between action potentials in a given PN and the field potential oscillations is lost; then, other subsets of PNs become synchronized. Computer models of the locust AL have suggested that the transient nature of PN synchronization could be explained by variations in inhibitory drive from inhibitory LNs over the duration of the odor-elicited response (Bazhenov et al. 2001a). Transient increases in feedback inhibition lead to increases in the timing precision of PN spikes.

Recent theoretical work led to a new strategy based on graph coloring theory to describe transient AL network dynamics (Assisi et al. 2011). In inhibitory neuronal networks, LNs that are not interconnected are given a particular “color”; these LNs can be active at the same time and can collectively inhibit LNs associated with a different color. In a model of the AL, these dynamics lead to alternating patterns of firing among groups

of LNs. This model of inhibitory network dynamics mediated by lateral inhibition between LNs can account for transient synchronization patterns of olfactory neurons in the AL. The role LN-LN inhibition may play in promoting competition among olfactory glomeruli has been also explored (Linster et al. 1994; Kerszberg and Masson 1995) and a model of olfactory memory based on altering lateral inhibition in the honeybee’s AL has been proposed (Linster and Masson 1996).

While the synchronization of PNs in the insects’ antennal lobe is eliminated by picrotoxin application, experiments performed *in vivo* have established that the slower firing pattern structures (alternating depolarizing and hyperpolarizing modes) are not affected by this treatment (MacLeod et al. 1998; Stopfer et al. 1997). In locusts, the origins of slow temporal patterning have been explored with electrophysiological studies and computational models. The patterns begin in olfactory receptor neurons, which respond to odors with a variety of simple firing patterns. The heterogeneity of these responses is an essential ingredient for the generation of more elaborate patterns downstream in the AL (Raman et al. 2010). In the AL, the slow inhibitory receptors between LNs and PNs, which operate with a time constant of a few hundred milliseconds, are essential for translating the simple but varying input received from the receptor neurons into the stimulus-specific slow temporal patterning of PN

responses (Bazhenov et al. 2001b). The sequences in which these modes appeared differ among PNs, and vary reliably with the stimulus. Relatively slow calcium and calcium-dependent potassium channels of PNs may further contribute to slow temporal patterning in the AL (Sivan and Kopell 2006).

What is the functional significance of the temporal structure in olfactory neuron responses? As shown in zebrafish (Friedrich and Laurent 2001) the slow temporal patterning in mitral cells appears to play a major role in the decorrelation of odor representations. The responses of a population of mitral cells to chemically similar odorants were highly correlated at the onset of the odor stimulation, but became progressively less correlated over the duration of the odor response. Recent computer modeling of the AL suggested that odor-specific evolution of PN activity can lead to an optimal encoding of the odor representation that decreases the overlap between odor-elicited PN spiking patterns (Assisi et al. 2012). This increases the ability of downstream neurons to discriminate between odors. A balance between inhibitory and excitatory connections mediated by local AL interneurons enhances the decorrelation of similar odors while keeping the representation robust in the presence of noise.

In insects, output from relatively small populations of olfactory neurons in the AL fans out broadly to large interneuronal ensembles in the mushroom body (Fig. 1). Fully half of all PNs synapse directly upon each KC, a connectivity scheme that maximizes the coding space available for odors (Jortner et al. 2007). Electrophysiological recordings indicate that Kenyon cells (KCs) of the mushroom body respond sparsely and specifically to odors: a given odor induces a brief response in only a small subpopulation of KCs (Perez-Orive et al. 2002). Mechanisms contributing to the specificity of this response include intrinsic nonlinear conductances in the KCs that respond best to coincident input from PNs, and inhibitory input from GGN (Papadopolou et al. 2011) that regulates the amount of firing in KCs (Fig. 1). Physiological and modeling results show the precise timing established by AL circuitry is

maintained not only within KCs, but also by their neural followers in the beta lobe (Cassenaer and Laurent 2007). Interestingly, odor specific timing precision is maintained in the beta lobe neurons, in part, by spike-timing dependent plasticity (STDP).

Computational models of the insect olfactory system have explored the proposal that AL circuitry reformats information about odors, distributing it into the identities of PNs responding to the odor, and into the relative timing of spikes in those PNs. Temporal features appear to become critical when discrimination tasks are more challenging, such as discriminating among PN ensembles that substantially overlap. Thus, the AL actively sharpens information about the olfactory stimulus by employing time and transient synchrony as coding dimensions. Understanding and testing hypotheses about these complex biological processes has been greatly facilitated by the use of computational models.

Olfactory Computation in Glomerular Microcircuits

Thomas A. Cleland
Computational Physiology Lab, Department of Psychology, Cornell University, Ithaca, NY, USA

Definition

The first, superficial computational layer of the vertebrate olfactory bulb consists of discrete spheroid clusters of neuropil known as glomeruli.

Within these glomerular microcircuits, primary olfactory sensory neuron axonal arbors interact with the dendrites of olfactory bulb principal neurons and multiple classes of local interneurons. The computations within and among these glomerular microcircuits determine how the primary sensory information arriving in the olfactory bulb is transformed prior to subsequent computations in the deep olfactory bulb and other regions of the brain. Among the important computations in the glomerular layer are a high-dimensional form of contrast enhancement and a competitive global normalization of activity levels across a population of second-order sensory neurons.

Detailed Description

The Olfactory Bulb

The olfactory bulb (OB) is the target of primary olfactory sensory neuron (OSN) axons that project across the blood-brain barrier at the cribriform plate (Fig. 1). Each OSN expresses, canonically, one type of odorant receptor protein from a family of hundreds (depending on species), and the specific receptor protein expressed determines the chemoreceptive field of that OSN. Critically, the axons of “sister” OSNs that express the same receptor converge together and arborize in the same location, forming a spheroid tangle of neuropil that is visible at the light microscopic level and known as a *glomerulus*. Inhaled odorants will bind to multiple odorant receptors with different affinities and hence will activate multiple glomeruli to differing degrees in patterns characteristic of that odor. These odor-specific patterns of glomerular activation are the basis for odor recognition.

Odor information is exported from the OB and propagated into the rest of the brain via mitral cells (Mi) and middle/deep tufted cells, the principal neurons of the OB. Importantly, while mitral cells can be activated directly by OSN input to glomeruli, the majority of their afferent excitation appears to be indirect, mediated via external tufted (ET) cell interneurons (Fig. 1). Mitral cell output also is strongly regulated by interactions with local interneurons within the glomerular-layer

Olfactory Computation in Glomerular Microcircuits, Fig. 1 Schematic diagram of glomerular microcircuitry in the olfactory bulb. Three different classes of olfactory sensory neuron in the olfactory epithelium (OE) of the nasal cavity project to three corresponding glomeruli (gray ovals) in the olfactory bulb glomerular layer (GL). Within each glomerulus, the sensory neurons activate principal neurons including mitral cells (Mi) and middle/deep tufted cells (not shown) as well as local interneurons including the excitatory external tufted (ET) cells and the inhibitory periglomerular (PG) and superficial short-axon

(sSA) cells. Some PG cells receive direct afferent input from olfactory sensory neurons (PGo), whereas the majority receive their afferent input indirectly via external tufted cells (PGe). PG and sSA neurons – particularly the latter – interconnect glomeruli nonspecifically, ultimately delivering broadly sourced feedback inhibition onto mitral cells (Banerjee et al. 2015) via intermediary ET cells (Whitesell et al. 2013). Deep bulbar circuitry (the interconnectivity of mitral cell lateral dendrites with granule cells) is not depicted

microcircuit (as well as a deeper layer of OB circuitry not discussed here) that transform these raw afferent representations; these local interactions also appear to act on mitral cells predominantly via ET cells (Whitesell et al. 2013). Specifically, as in other sensory systems, these early transformations of olfactory inputs include (1) the dynamic sharpening of primary sensory representations (Cleland 2010), (2) mitigation of the confounding effects of stimulus intensity (i.e., odorant concentration; Cleland et al. 2011), and (3) the constraining of absolute input intensity to levels that can be managed by follower circuitry. Unlike other sensory systems, however, the similarity space in which olfactory representations are embedded is computationally high-dimensional. Hence, similarity-dependent computations such as contrast enhancement (aka sharpening of the representation, a form of signal decorrelation) require algorithmic solutions capable of

computing in high-dimensional spaces. These solutions are implemented in the microcircuitry of the OB glomerular layer.

High Dimensionality

The high dimensionality of the system arises from the diversity of primary odorant receptors and the lack of a common physical basis function by which to organize their receptive fields. The chromatic receptive fields of the three types of cones in the human retina share the common basis of wavelength, and the diverse receptive fields of auditory hair cells all can be mapped along a one-dimensional basis of auditory frequency, but the receptive fields of olfactory receptors are essentially arbitrary with respect to one another. Given that, for any pair of odorant receptors, a ligand exists that will activate one and not the other, each odorant receptor type must be treated as independent. The similarity space that can contain all

possible odorant inputs therefore has the same dimensionality as the number of different odorant receptor types expressed – over 1000 in mice, roughly 350–400 in humans.

Critically, of course, not all possible odorant inputs or combinations thereof are equally likely. In any given, finite universe of odorants, the dimensionality of odor space can be reduced, often substantially. (Indeed, the putative dimensionality of olfactory similarity space has been measured in some studies, though the results obtained in these studies have more to do with the particular, limited set of odorants selected than with the nature of the olfactory system *per se*). A corollary of this principle is that any quantitative description of olfactory similarity space depends on the statistical structure of the olfactory environment – that is, how likely is it that any given odorant from this environment will differentially activate any given pair of odorant receptors? If the olfactory system is to be able to interpret any possible combination of receptor inputs received, then the high dimensionality of the input space is unavoidable.

Glomerular Microcircuitry

In general, each half of each OB in mice contains one glomerulus for each olfactory receptor type, to which the converging axons of that family of OSNs project (Mombaerts 2006). Because the high dimensionality of the olfactory similarity space cannot be continuously projected onto the two-dimensional surface of the OB, physical proximity cannot serve as a proxy for receptive field similarity as it can, for example, in the retina or the cochlear nucleus. The classical algorithm, nearest-neighbor lateral inhibition, therefore can be ruled out as an effective solution for olfactory contrast enhancement.

Instead, each intraglomerular microcircuit effectively generates its own inhibitory surround in olfactory similarity space by generating feed-forward inhibition of its own mitral cells that successfully inhibits excitatory throughput when the glomerulus is weakly or moderately activated, but that is overcome by direct OSN-to-mitral excitation when the glomerulus is strongly activated. That is, stimulation in the center of the chemoreceptive

field is propagated, whereas stimulation at the edge of the chemoreceptive field is inhibited below baseline. By eschewing competitive connections among different glomeruli, this non-topographical contrast enhancement algorithm is independent of olfactory dimensionality and will function irrespective of how many different olfactory receptors exist and irrespective of the comparative similarities of their receptive fields in any given environmental context (Cleland and Sethupathy 2006; Fukunaga et al. 2014). Moreover, the degree of sharpening produced by this microcircuit can be dynamically regulated by top-down inputs, such as cholinergic neuromodulation (Chaudhury et al. 2009; D'Souza and Vijayaraghavan 2012).

Non-topographical contrast enhancement uses relative levels of afferent excitation at each glomerulus as a proxy for ligand-receptor potency at the corresponding olfactory receptor and hence depends upon the global normalization of input activation levels across glomeruli to mitigate the confounding effects of concentration. Global feedback normalization preserves relational patterns of activity among glomeruli while also serving to constrain absolute afferent input levels within the relatively narrow dynamic ranges of follower neurons. In the OB, several mechanisms appear to contribute to the latter goal of matching absolute input activity levels to the needs of follower circuitry while preserving sensory information (Cleland et al. 2011); one of these in particular also underlies the competitive global normalization necessary to generate relational representations (Cleland et al. 2007; corrected implementation in Banerjee et al. 2015). Specifically, glomeruli across the OB are interconnected by a heterogeneous, laterally projecting network of GABAergic/dopaminergic periglomerular (PG) and superficial short-axon (SSA) cells.

Note that the nomenclature of these glomerular-layer inhibitory interneurons is evolving. The majority of these neurons express GAD67 and DAT and release both GABA and dopamine. This population is morphologically diverse and sometimes is treated as a single heterogeneous class (e.g., the DAT+ neurons of Banerjee et al.

2015), comprising most of the classically defined PG neurons and all of the classically defined sSA neurons. More recent work has established a clearer class difference within this heterogeneous population that corresponds reasonably to distinct PG and sSA cell types; specifically, GAD67+/DAT+ neurons with large somata and axons correspond to the sSA class, while those with smaller somata and no axon initial segment correspond reasonably to the PG class (Galliano et al. 2018). The PG class can be subdivided further into PGe and PGo subtypes by virtue of whether or not they receive direct input from the olfactory nerve (Fig. 1). Finally, a separate, smaller class of GAD65+, non-dopaminergic interneurons also is often grouped into the PG cell category and may contribute to both PGe and PGo morphological subtypes (discussed in Sethupathy et al. 2013).

Activation of these neurons inhibits mitral cells broadly across the OB, thereby feeding back a globally averaged level of inhibition across the mitral cell population that can mediate gain control (Banerjee et al. 2015). This operation constrains the dynamic ranges of absolute MC activation levels, thereby fulfilling a necessary prerequisite for non-topographical contrast enhancement (Cleland et al. 2007).

Summary

Glomerular microcircuitry in the OB is able to regulate the sharpening of sensory representations and normalize absolute input intensities so as to deliver more consistent and reliable sensory information to the neural circuitry of the deep OB, as well as to extrabulbar follower regions such as the anterior olfactory nucleus, piriform cortex, and olfactory tubercle. Additionally, lateral projections by ET cells selectively connect “sister” glomeruli (associated with the same odorant receptor type) across the OB and modulate the response properties of associated mitral cells (Zhou and Belluscio 2008). External tufted cells also are intrinsically resonant at roughly respiratory frequencies, bursting rhythmically when activated (Hayar et al. 2004), and may serve to temporally coordinate strongly activated and weakly

activated regions of the OB. Mitral cells also are intrinsically resonant, but at a faster beta-band frequency (Desmaisons et al. 1999); their resonance may govern the transformation of OB output into an energetically efficient metric based on spike timing that is relevant to computations within deep OB circuitry (Li and Cleland 2017) and potentially plastic. The essential function of glomerular layer microcircuitry appears to be to manage the physical complexities of odorant inputs, such as high dimensionality and uncontrollable stimulus intensities, thereby transforming afferent odor representations into a more manageable, diagnostic, and energetically efficient form.

Definition

Olfactory computation in mitral-granule cell circuits refers those operations between mitral and granule cells that can directly modulate the mitral cell firing behavior. In vertebrates, they are carried out by the reciprocal synapses established

between mitral cells' lateral dendrites and spines on granule cell dendrites (Shepherd 2004).

Detailed Description

Mitral-granule cell circuits are formed by the continuous and dynamic reconfiguration of their synaptic connections during the entire life of the organism. Although, to date, there is no direct experimental evidence for plasticity of these synaptic connections, their sparse and distributed nature is well established (Willhite et al. 2006) and widely acknowledged as being the main mechanism responsible for the lateral inhibition effects observed in the olfactory bulb (Yokoi et al. 1995). This entry focuses on the circuitual aspects of the mitral-granule reciprocal synapses, rather than on how they can be established or destroyed through LTP/LTD or cells' turnover processes. All mitral-granule circuits are activated by a canonical sequence of steps, in which (a) an odor input facilitates one or more mitral cell somatic action potentials (APs); (b) these APs backpropagate along the lateral dendrites, releasing glutamate thereby activating granule cells along their way; and (c) granule cells locally inhibit the lateral dendrites of the mitral cells to which they are connected. The relative location of the activated granule cell with respect to the soma of a mitral cell can generate different circuits with different computational properties, such as (1) *distance-independent lateral inhibition*, (2) *synchrony*, and (3) *gating effects*.

Distance-Independent Lateral Inhibition

While granule cells connect to dendrodendritic synapses along the full span of the lateral dendrites, the inhibition from any granule cell onto the mitral cell is local. As such, those granule cells near to the mitral cell soma can more easily regulate its firing than those far away. The implication for one mitral cell to strongly laterally inhibit another is that the granule cell shared between the two mitral cells must be near to the soma of the target neuron. While inhibition is local, because of the broad field of granule cells,

Olfactory Computation in Mitral-Granule Cell Circuits, Fig. 1 Distance-independent lateral inhibition. Inhibition can be independent of the relative distance between mitral cells (*M0* and *M1*) if it is imposed locally by granule cells (*GC0* and *GC1*) activated by a

backpropagating action potential (*bAP*). In this simulation an action potential was generated on *M0* (red trace). Its backpropagation activated *GC1* (closed red circle on *GC1*), generating an inhibitory response (open red circle on *GC1*) close to the soma of *M0* (black trace)

there is a population of granule cells that will be near to the body of any given mitral cell, and the circuit can ironically obtain distance-independent lateral inhibition. This is schematically shown in Fig. 1, where the synapses relevant to the circuit are highlighted in red (excitatory and inhibitory synapses are represented by closed and open circles, respectively). A somatic action potential elicited in *M0* backpropagates (*bAP*) along the *M0* lateral dendrites (in red). It activates both *GCs* (closed red circles), but the consequent inhibition (open red circles) on *M1* (black trace) is mainly determined by *GC1*, which is close to the soma and independent from the location of *M0*, provided that the AP can backpropagate along the lateral dendrite.

Synchrony

When two similar neurons receive a correlated signal, they can synchronize. If two mitral cells are near each other and share granule cells near their somas, they will mutually inhibit each other and synchronize. Similarly, if the two mitral cells in Fig. 1. were activated by an odor, they provide a correlated signal onto their shared granule cells. As such, the granule cells become synchronized and provide a correlated signal onto the mitral cells, which might be widely separated. Such synchrony is reliant on backpropagating

action potential travelling the full span of the lateral dendrites. However, this may not always be the case. A typical circuit exhibiting this effect is shown in Fig. 2. The two mitral cells receive the same input, but starting at different times. At $t = 500$ ms the granule cells are activated and the mitral cells synchronize.

Gating Effects

Gating effects occur when the backpropagation of action potentials is blocked by the local (dendritic) inhibition activated by other mitral cells. A typical example is illustrated in Fig. 3, with three mitral cells (*M0–M2*) and three granule cells (*GC0–GC2*). All mitral cells receive the same odor input with different latency, and only the mitral-granule synapses relevant to this circuit are highlighted in red (excitation and inhibition are represented by closed and open circles, respectively). The plots show membrane potential of *M0–M2* soma and lateral dendrite of *M0* at 800um from the soma during simulations with *GC1* active or inactive. Note that the firing of *M2* (blue traces) depends on *GC1* local activation through *M1* (black trace close to *GC1* soma). In this case (top traces), the backpropagation of the APs along the *M0* lateral dendrite (black traces) is blocked by *GC1*

Olfactory Computation in Mitral-Granule Cell Circuits, Fig. 2 Mitral cells synchronization. Two mitral cells (*M0* and *M1*) were activated by the same input, but starting with a 20 ms relative latency. At $t = 500$ ms the granule cells (*GC0* and *GC1*) were activated and the mitral

cells synchronized (*black* and *red* traces). The reciprocal synapses involved in this circuit are shown in *red*, with excitation and inhibition represented by *closed* and *open circles*, respectively

Olfactory Computation in Mitral-Granule Cell Circuits, Fig. 3 Gating effects. Three mitral cells (*M0–M2*) receive the same odor input with different latency. The plots show somatic potential of *M0–M2* (traces above the soma) and the membrane potential of the *M0* lateral

dendrite (in *black*) at 800 mm from the soma (traces indicated with *dotted lines*), during simulations with *GC1* active or inactive. The reciprocal synapses involved in this circuit are shown in *red*, with excitation and inhibition represented by *closed* and *open circles*, respectively

activity, *GC2* will not be activated, and *M2* can fire APs. With *GC1* inactive, APs from *M0* can freely backpropagate until they activate *GC2*, inhibiting *M2*.

Interactive simulations of the circuits illustrated in Figs. 1, 2, and 3 can be downloaded from the ModelDB section of the Senselab database suite (<http://senselab.med.yale.edu/>, accession number 149415).

Definition

The olfactory provides an ideal system to explore the proprieties of associative networks, like storage and retrieval of memory patterns, for a number of reasons: its principal cells share many of the fundamental proprieties with associative networks; the system is only one synapse away from its main sensory input, facilitating experimental manipulation in animals; and the olfactory cortex shares many similarities with other well-known associative systems of learning and memory, like the hippocampus.

Detailed Description

Associative Networks

Associative networks are among the most fundamental group of neural networks in the brain, enabling the storage, retrieval, and association of complex patterns of neuronal activation. These features, for instance, provide the brain the ability to correlate independent events, reconstruct previously learned patterns from fragmented or distorted inputs, and elicit outputs from previously stored patterns using novel inputs.

One important characteristic of these associative networks is the capacity of some of its neurons to change the strength of the connection between elements (neurons) based exclusively in local conditions like the level of synchronization of inputs converging to these neurons. Another characteristic is the fact that memories are “spread” over the neural network so that individual connections between neurons participate in the storage of different memories (Haberly and Bower 1989; Rolls and Treves 1994, 1998).

In general, associative networks can be roughly divided in two distinct groups: hetero-associative networks, where the associations occur between different, but interconnected, networks and autoassociative networks, where the associative connections are recurrent, exciting neurons within the network (Rolls and Treves 1998). However, it’s important to keep in mind that these definitions many times blend together, where autoassociative networks will also interact with other neural networks creating hetero-associative connections. Figure 1 was adapted from Haberly (2001) and shows examples of the dynamics in heteroassociative networks (Fig. 1A) and autoassociative networks (Fig. 1B).

Figure 1A shows a structure composed by a pair of reciprocally connected networks being used for pattern correlation. During the learning step (Fig. 1Ai), network 1 is activated by the input pattern 1 at the same time that neurons in network 2 are excited by input 2. The temporal co-activation of these two neuronal groups increases the weights of the synapses between

Olfactory Cortical Associative Memory Models, Fig. 1 Examples of associative networks. (A) Heteroassociative network composed by two interconnected networks. (Ai) Networks 1 and 2 represent two different regions in the brain. When patterns 1 and 2 are activated at the same time, the synapses between the active neurons (black) undergo Hebbian potentiation and have their synaptic weights increased (represented by the + sign), while other synapses remain unchanged. (Aii) During the recalling step, only pattern 2 was presented, activating neurons d and f in network 2. (Aiii) However, the activation of d and f is enough to evoke the learned firing patterns

in network 1 as well. (B) In autoassociative networks, each neuron makes recurrent connections that contact other neurons in the network. (Bi) The network receives an input pattern where neurons a, b, and c are activated. The co-activation potentiates the synapses between these cells. (Bii) After learning, the network receives a corrupted or altered version of the original input. The activation of neurons a and c helps the autoassociative connections to fire neuron b recovering the original pattern activation, a process known as *pattern completion* (These figures were adapted from Figs. 4 and 5 in Haberly (2001))

firing neurons (represented in Fig. 1Ai by the synapses with + signs), a process known as Hebbian potentiation. On the other hand, this potentiation doesn't occur between neurons that were not co-active (e.g., neurons a and d, in Fig. 1Ai). Over time and a series of repetitions, these synapses become strong enough to recall

the firing pattern even if only one of the inputs is active, as shown in Fig. 1Aii, Aiii. Architectures of this kind allow neuronal activations in one area of the brain to become functionally joined to an unrelated pattern in a different area so that the occurrence of one pattern reconstructs the other.

Figure 1B illustrates the dynamics of an auto-associative network, where neurons make excitatory connection within the network. Figure 1Bi shows the neuronal response to a novel input pattern. The synapses of active neurons undergo Hebbian potentiation while the connections between active and inactive neurons remain unaltered. When a partial (or corrupted) pattern is provided to the network, it directly excites a subset of the cells that represent a memory, as shown in Figure 1Bii; then, through the recurrent excitatory connections reinforced during the learning step, these cells excite all the cells that represent the memory, notably those that did not receive direct input from the partial pattern (Fig. 1Biii), in a process known as *pattern completion*. This repair process is possible because the memory is so redundantly encoded that the still active cells can reactivate the neurons that stop firing (Marr 1971; Hopfield 1982). It also provides some level of robustness to errors and other external perturbations to a given memory.

Olfactory Cortex as a Model for Associative Memory

In Haberly and Bower (1989), the authors present a series of arguments about why the olfactory cortex (OC) provides an ideal system for the study of associative memory functions:

- Pyramidal cells (Pyr), the principal cells in the OC circuitry, share many of the fundamental proprieties with associative networks. These cells receive inputs and send outputs to the olfactory bulb and many high-order areas of the cortex, indicating that the system might integrate and associate olfactory information with other sensorial components (Shipley and Geinisman 1984; Schoenbaum and Eichenbaum 1995; Johnson et al. 2000; Sosulski et al. 2011). Besides that, the primary axons of Pyr cells in some subregions of the olfactory cortex give rise to a profusion of collateral branches that connect to other local Pyr cells (Haberly and Shepherd 1973; Price 1973), similar to the autoassociative network in Fig. 1B.
- The OC is only one synapse away from the olfactory sensory neurons, responsible for the transduction of the odor molecules to action potentials. This proximity to its main sensory inputs is extremely convenient for experimental analysis. Besides that, Pyr cells display a remarkable laminar segregation of inputs from different neuronal groups, for example, afferent inputs are restricted to distal apical dendrites while association connections with other Pyr cells are centered in more proximal portions of the apical dendrites (Haberly 2001).
- The OC receives cholinergic inputs from the horizontal limb of the diagonal band of Broca (HDB) (Brashear et al. 1986; Zaborszky et al. 1986). Acetylcholine (ACh) is shown to affect the activation of Pyr cells and other neurons in the OC (Tseng and Haberly 1989; Barkai and Hasselmo 1994), as well as excitation and synaptic plasticity in associative connections between Pyr cells (Williams and Constanti 1988; Hasselmo and Bower 1992; Hasselmo and Barkai 1995; Patil et al. 1998). Behaviorally, cholinergic modulation has been linked to changes in the odor memory formation in the OC (Wilson 2001; Barkai 2005; Linster et al. 2009).
- There are many parallels between the OC and the entorhinal-hippocampal system, a region that is believed to play an important role in learning and memory. For instance, both systems are organized as a distributed network, with different areas performing distinct sets of operations in parallel; both systems present a broad overlapping spatial organization rather than the columnar pattern organization presented in deeper layers of the neocortex; the systems also present a forward flow of information from their input structures (olfactory bulb for the OC and entorhinal cortex for the hippocampus) and back projections connecting the different structures in the information streams. A detailed description of the parallels between the OC and the hippocampal system and the OC and other cortical regions can be found in Haberly (2001).

Example of a Model of Olfactory Cortical Associative Memory

The example presented here was published in de Almeida et al. (2013). This model investigates the influence of cholinergic modulation in the olfactory bulb (OB) and impact of this modulation in the formation of odor memories in the piriform cortex (PC). The PC is the largest area of the OC and shares many similarities with the other areas of the OC (Haberly and Bower 1989). The model presented here is restricted to the PC network; the OB model is out of the scope of this article. However, a detailed description of both models can be found in de Almeida et al. (2013), and source code of these models (implemented in MATLAB programming language) can be downloaded from the modelDB website (Hines et al. 2004).

Network Architecture

The model is composed by one group of principal cells (Pyr cells) and two groups of inhibitory interneurons, defined as feed-forward cells (Ff) and feedback cells, as shown in Fig. 2.

The PC network receives projection from mitral cells in the OB. These projections are assumed to randomly connect to Pyr neurons (Linster et al. 2009; Stokes and Isaacson 2010). The two groups of inhibitory interneurons modulate the activity of Pyr cells. In vivo recordings of excitatory and inhibitory postsynaptic currents show that Ff interneurons are activated by many different odorants, in contrast to Pyr neurons whose activation is much more odorant specific (Poo and Isaacson 2009; Isaacson 2010; Stokes and Isaacson 2010). In the model, Pyr cells receive input from 20% of the mitral cell inputs (Linster et al. 2009) and are inhibited by 30% of the Ff network, as measured by Stokes and Isaacson (2010). Ff cells, however, receive excitatory inputs from a larger number of mitral cells (40%) than the Pyr cells. The second group of interneurons, the Fb cells, is recruited by the activation of Pyr cells and sends its inhibitory projections back to the same group of Pyr neurons. Each Fb cell is excited by 18% of the Pyr network,

Olfactory Cortical Associative Memory Models, Fig. 2 Simplified structure of the piriform cortex (PC).

The system receives excitatory input from mitral cell axons in the OB. These axons connect to pyramidal (Pyr) and feed-forward (Ff) cells. Pyramidal cells work as an auto-associative network, projecting their axons to other Pyr neurons and to feedback (Fb) cells. This last group of interneurons then makes inhibitory synapses to the Pyr cells (Stokes and Isaacson 2010)

and each Pyr cell is inhibited by 35% of the Fb network (Stokes and Isaacson 2010).

Model Equations

All cells in the network are represented as single-compartment leaking integrate and fire neurons (Abbott 1999; Dayan and Abbott 2001), where the evolution of the membrane voltage is described by a first-order differential equation:

$$\tau \frac{dv(t)}{dt} + v = V^{ext}(t) \quad (1)$$

where τ is the membrane time constant and $V^{ext}(t)$ is the total external input over time. The input coming from a given presynaptic neuron at time t is a function of the synaptic strength W_{ij} , the conductance change $g_i(t)$ in cell i , and the

General parameters (shared by all neurons)	$v^{\text{hyper}} = -10 \text{ mV}; \theta^{\text{min}} = -2 \text{ mV}$
Pyramidal cell (Pyr)	$t^{\text{refrac}} = 2 \text{ ms}; \tau = 10 \text{ ms}; \beta = 10; \theta^{\text{max}} = 17 \text{ mV}$
Feed-forward cell (Ff)	$t^{\text{refrac}} = 2 \text{ ms}; \tau = 5 \text{ ms}; \beta = 5; \theta^{\text{max}} = 17 \text{ mV}$
Feedback cell (fb)	$t^{\text{refrac}} = 2 \text{ ms}; \tau = 5 \text{ ms}; \beta = 5; \theta^{\text{max}} = 17 \text{ mV}$
Mitral input to pyramidal cell	$g^{\text{max}} = 0.84; E_N = +70 \text{ mV}; \tau_1 = 1 \text{ ms}; \tau_2 = 2 \text{ ms}$
Mitral input to feed-forward cell	$g^{\text{max}} = 2.4; E_N = +70 \text{ mV}; \tau_1 = 1 \text{ ms}; \tau_2 = 2 \text{ ms}$
Feed-forward inhibition	$g^{\text{max}} = 0.056; E_N = -10 \text{ mV}; \tau_1 = 4 \text{ ms}; \tau_2 = 8 \text{ ms}$
Feedback inhibition	$g^{\text{max}} = 0.8; E_N = -10 \text{ mV}; \tau_1 = 4 \text{ ms}; \tau_2 = 8 \text{ ms}$
Pyramidal to feedback cell	$g^{\text{max}} = 0.8; E_N = +70 \text{ mV}; \tau_1 = 1 \text{ ms}; \tau_2 = 2 \text{ ms}$
Pyramidal cell association fibers	$g^{\text{max}} = 5.0; E_N = +70 \text{ mV}; \tau_1 = 1 \text{ ms}; \tau_2 = 2 \text{ ms}$

difference between the Nernst potential $E_{N,ij}$ of the specific channel type and the current membrane potential $v_j(t)$ of the postsynaptic neuron j , as described in Eq. 2:

$$V_j^{\text{ext}}(t) = W_{ij} g_{ij}(t) [E_{N,ij} - v_j(t)] \quad (2)$$

The communication between neurons in the network occurs through discrete action potentials that are a function of the membrane potential:

$$F_i(V) = \begin{cases} 0 & \text{if } V \leq \theta^{\text{min}} \\ \left(\frac{V - \theta^{\text{min}}}{\theta^{\text{max}} - \theta^{\text{min}}} \right) & \text{if } \theta^{\text{max}} < V < \theta^{\text{min}} \\ 1 & \text{if } V \geq \theta^{\text{max}} \end{cases} \quad (3)$$

where $F_i(V)$ represents the continuous output (for OSNs and PGs) or the instantaneous spiking probability (for the remaining neuronal groups). θ^{min} and θ^{max} represent the minimum threshold and the saturation threshold of the output/probability function, respectively. β defines the nonlinearity of $F_i(V)$. Finally, $g_i(t) = g(t - t_i^{\text{fire}})$ represents the time course of the conductance given by Eq. 4:

$$g(t) = g^{\text{max}} \left(e^{\frac{-t}{\tau_1}} - e^{\frac{-t}{\tau_2}} \right) \quad (4)$$

where τ_1 and τ_2 are, respectively, the rising and falling times of the conductance and g^{max} is a constant with no unit representing the maximum conductance of a given channel. After firing, the voltage of each spiking neuron is reset to a hyperpolarization potential v^{hyper} and remains inactive

for a refractory period t^{refrac} ; for details on the parameters, see Table 1.

The synaptic modifications of the pyramidal associative fibers were implemented using a Hebbian learning similar to that proposed by Jensen et al. (1996), where the synaptic efficiency is enhanced if both pre- and postsynaptic neurons fire together and reduced if not. Each Pyr-Pyr connection has a synaptic weight initially set to a random minimal value between zero and 0.02, which is approximately 10% of the average maximum W observed in after one training session in the network. The synaptic enforcement has been shown to depend on NMDA receptors that allow the influx of Ca^{2+} , as long as sufficient postsynaptic depolarization is provided. The rise of Ca^{2+} triggers a cascade of events that ultimately results on a long-term potentiation in AMPA- and NMDA-mediated synaptic responses (Bliss and Collingridge 1993). The model assumes that the postsynaptic depolarization is attributed to back propagation from the action potential of the postsynaptic cell described by Eq. 5:

$$i^{\text{post}}(t) = \frac{t}{\tau^{\text{post}}} \exp \left(1 - \frac{t}{\tau^{\text{post}}} \right) \quad (5)$$

where the time course of this depolarization at the postsynaptic neuron (τ^{post}) is 2 ms.

The kinetics of NMDA channels depends on the binding of glutamate on the receptors. In the model, its time course is described by Eq. 6:

$$b^{\text{glu}}(t) = \exp \left(-\frac{1}{\tau^{\text{NMDA}f}} \right) \left(1 - \exp \left(-\frac{1}{\tau^{\text{NMDA}r}} \right) \right) \quad (6)$$

where $\tau^{NMDA^f} = 7$ ms and $\tau^{NMDA^r} = 1$ ms characterize the kinetics of NMDA receptors. Finally, the synaptic enhancement between neurons i and j is described by Eq. 7:

$$\frac{dW_{ij}^{syn}}{dt} = (1 - W_{ij}^{syn}) \frac{t_j^{post}(t - t_j^{fire}) b_j^{glu}(t - t_j^{fire} - t^{delay})}{\tau^{pp}} + (0 - W_{ij}^{syn}) \left(\frac{t_j^{post}(t - t_j^{fire})}{\tau^{pp}} + \frac{b_j^{glu}(t - t_j^{fire} - t^{delay})}{\tau^{np}} \right) \quad (7)$$

where t^{delay} is the time it takes an action potential to travel from the soma to the synapses of a recurrent collateral. If t_j^{post} and b_j^{glu} peak together, the synaptic weight between neuron i and j is driven to one with the characteristic time τ^{pp} (50 ms); if the events are asynchronous, the synaptic efficacy is decreased with time τ^{np} ($\tau^{pp} = \tau^{np} = 250$ ms).

Different Models of Associative Network in the OC

Several models have been proposed to explore the associative memory functions necessary for odor learning in the OC (Haberly and Bower 1989; Ambros-Ingerson et al. 1990; Hasselmo et al. 1990). More specifically, many research groups proposed computational models exploring how the cholinergic modulation regulates the acquisition of odor memories in the OC. ACh suppresses neuronal adaptation and excitatory synaptic transmission between Pyr cells while promoting long-term potentiation (LTP) between these synapses (Williams and Constanti 1988; Hasselmo and Bower 1992, 1993; Barkai and Hasselmo 1997). These results provided a theoretical framework for linking the neuropharmacological effects of acetylcholine to a role in memory function, where two distinct scenarios are observed: a *learning mode* where ACh modulation in the OC is ON and a *recalling mode*, where ACh modulation is OFF. The possible effects of this modulation in associative networks were investigated in Hasselmo et al. (1992), Hasselmo and Barkai (1995), Liljenstrom and Hasselmo (1995), Barkai and Hasselmo (1997), Linster and Hasselmo (2001), Linster et al. (2003, 2009).

Besides ACh, the impact of other neuromodulators in associative networks of the OC was, so far, little explored. One exception is noradrenaline, whose role in the OC was explored in a computational model in Hasselmo et al. (1997). According to the authors, noradrenergic modulation appears to enhance the encoding of sensory inputs and suppress excitatory transmission of associative connections between Pyr cells, effects somewhat similar to ACh modulation.

[Dose-response functions](#); [Concentration-response functions](#); [Activation of the olfactory sensory neurons as a function of odor concentration](#)

Definition

Mathematical modeling of the response of olfactory sensory neurons (OSNs) to odor stimuli refers to models able to predict the OSNs response to a mixture of N odorants ($N \geq 2$) starting from the responses to individual components.

Detailed Description

Most real-world odors are complex mixtures consisting of dozens, often hundreds of components, and olfactory systems have evolved to recognize and discriminate them. The sensory process starts with the interaction of odorant molecules with the olfactory receptors (ORs) located on the cilia of olfactory sensory neurons (OSNs). The ORs occupy a small area in the upper part of the nasal epithelium and detect the inhaled odorant molecules. Although the detection of an odor molecule in the environment is primarily a chemical and biochemical process, the signal which is sent to the brain announcing this detection is transduced into electrical activity. Indeed, the odorant molecules binding to receptors activate specific *G-proteins* that initiate a cascade of intracellular signaling events leading to the generation of an action potential that is propagated along the olfactory sensory axon to the olfactory bulb of the brain (Buck and Axel 1991; Firestein and Shepherd 1991). The axons of the olfactory bulb neurons, in turn, project to subcortical and cortical regions where higher-level processing of olfactory information allows the discrimination of odors by the brain (see Fig. 1).

In this entry we focus on initial event of olfactory perception, that is, the interactions of odorant molecules to ORs and then the activation of the OSNs as a function of the odor concentration (i.e., a dose-response function). It has been widely demonstrated that, in most cases, the response of OSNs to (single) odor stimuli can be conveniently reproduced by a *sigmoidal shape* with concentration, usually implemented as a *Hill function*. Moreover, the dose-response curve for a *binary odor mixture* at a fixed concentration ratio is still of sigmoidal shape in most

cases, and it is usually compared with the curves for the individual components. However, the response to a mixture of odorants is not a simple function of the response to the individual components, and its properties are empirically classified as follows (Fig. 2):

Suppression, when the response to the mixture is between the response to the single components.

Synergy, when the response to the mixture is higher than both components.

Inhibition, when the response to the mixture is lower than both components.

Hypoadditivity, when the response to the mixture is similar to the most effective component.

Overshadowing, when the response to the mixture is similar to one of the components.

In literature were proposed different models to determine the responses of olfactory sensory neurons to odor (binary) mixtures from the responses to the individual components (Rospars et al. 2008; Cruz and Lowe 2013; Marasco et al. 2016). In particular, the models proposed in Rospars et al. (2008) and Cruz and Lowe (2013) are able to reproduce all cases of suppression, but it can be mathematically demonstrated that they cannot reproduce mixtures exhibiting synergy, and inhibition, at least in the region of the maximum response (Marasco et al. 2016). Moreover, in Rospars et al. (2008) and Cruz and Lowe (2013), it has been assumed that the Hill coefficient, describing cooperative effects in the transduction cascade, is a property of the neurons instead of the odors. However, there are experimental findings showing that the response of the same OSN to different odorants may exhibit different Hill coefficients (Pongrácz et al. 1993; Wachowiak and Cohen 2001).

Recently in Marasco et al. (2016) has been proposed a mathematical model able to predict all types of mixture interactions among N odorants (with $N \geq 2$). In this model all the typical, experimentally measurable, characteristics of the dose-response curves (i.e., steepness, midpoint, and asymptotic value) can be

Olfactory Sensory Neurons to Odor Stimuli: Mathematical Modeling of the Response, Fig. 1 The human olfactory system (Press Release 2004), © The Nobel Assembly at Karolinska Institutet]

mathematically expressed by a nonlinear combination of the parameters for the individual components. Furthermore, it is shown that it is possible to find suitable mathematical conditions for all parameters and concentrations, in such a way to make it possible to design mixtures with specific properties. The results suggest a way to predict the overall behavior of a receptor type in response to a mixture composed of any number of components, provided that the individual response curves and their relative concentration ratios are known. A rigorous analysis of the mathematical structure of the three-dimensional *odor response space* (ORS) suggests that any dose-

response curve of an odor receptor can be obtained as a combination of three (out of four) *primary odor responses* with specific properties, opening the way to an objective procedure to obtain specific olfactory receptor responses by manipulating mixtures in a mathematically predictable manner.

Mathematical Models for the Response of OSNs to Single Odors and Mixtures

In this section, we present the models proposed in literature (Rospars et al. 2008; Cruz and Lowe 2013; Marasco et al. 2016) to describe the responses of OSNs to single odors and mixtures.

Olfactory Sensory Neurons to Odor Stimuli: Mathematical Modeling of the Response, Fig. 2 Typical set of odor response to single odors (F_U and F_V) and their binary mixture (F_{U+V}) (Marasco et al. 2016)

Kinetic Schemes and Assumptions Underlying Rospars et al. (2008) and Cruz and Lowe (2013) Models

Rospars et al. model (Rospars et al. 2008) is based on the following kinetic reactions describing the odorant molecules that bind to the ORs and activate them

where k_{1U} , k_{-1U} are the binding (association) and release (dissociation) rate constants, R_U is the bound receptor-ligand complex, and R_U^* is the activated complex.

In this scheme the receptors can be in three states: free R , bound R_U , and activated R_U^* , and the total constant concentration of receptors is $R_T = R + R_U + R_U^*$. At equilibrium the system

of differential equations relative to reactions (1) leads to the concentration of the activated complex as a function of odorant concentration (Rospars et al. (2008), Supplemental notes)

$$R_U^* = \frac{R_{MU}^*}{1 + \frac{K_U}{U}} \quad (2)$$

where $K_{1U} = \frac{k_{-1U}}{k_{1U}}$ and $K_{2U} = \frac{k_{-2U}}{k_{2U}}$ are the equilibrium dissociation and deactivation constants, and

$$R_{MU}^* = \frac{R_T}{K_{2U} + 1}, K_U = \frac{K_{1U}K_{2U}}{K_{2U} + 1} \quad (3)$$

Moreover, the effect of the transduction cascade interposed between the ORs activations and the measured OSNs responses is modeled as a transformation that maps the *hyperbolic function* (2) with the Hill coefficient $n = 1$ into a *Hill*

function with $n \neq 1$ followed by a linear transformation (see Eq. 5₁).

The binary mixture model proposed in Rospars et al. (2008) is obtained as an extension of the single odorant model in which the molecules of two different odorants U and V compete for the same receptors R . We recall that the *competitive interaction* arises when two or more ligands can bind to the same receptor binding site, although only one can be bound at a time. This mechanism could involve either two *agonist* odorants, i.e., molecules that are able to activate the receptor, or one agonist and one *antagonist* (the latter being a molecule that binds to the receptor but is unable to activate it). Nevertheless, experimental data suggests that both competitive and non-competitive interactions occur at the OR level (Rospars et al. 2008; Cruz and Lowe 2013). Then, assuming that the receptors can be bound and activated by both U and V according to reactions (1) for U and equivalent reactions for V , instead of (2) we obtain

$$R_{U+V}^* = \frac{R_{MU}^* \frac{U}{K_U} + R_{MV}^* \frac{V}{K_V}}{1 + \frac{U}{K_U} + \frac{V}{K_V}}, \quad (4)$$

where R_{MU}^* , R_{MV}^* , K_U , and K_V are given by Eq. 3.

Then, by analogy with the case of single odorants, to model the OSN responses to binary mixture, the authors introduced a Hill coefficient n (see Eq. 5₂). We remark that in this approach the Hill coefficient n is the same for both compounds appearing in the mixture, i.e., *the Hill coefficient n characterizes the OSN and it is independent of the odorants*.

In Cruz and Lowe (2013), following the kinetic schemes of Rospars et al. (2008), the authors empirically model the activation of the olfactory sensory neurons via the transduction cascade (see Eq. 9₂). In particular, the case of a single odorant U is obtained setting $V = 0$ in the dose-response function for competitive binary mixture (see Eq. 9₁). Also in this case, the Hill coefficient appearing in the binary mixtures model characterizes the OSN and it is independent of the odorants.

Rospars et al. Models

In Rospars et al. (2008), the authors proposed the following models for the response of OSNs to single odors and binary mixtures

$$F_U = \frac{F_{MU}}{1 + \left(\frac{K_U}{U}\right)^n},$$

$$F_{U+V}(U, V) = \frac{F_{MU} \left(\frac{U}{K_U}\right)^n + F_{MV} \left(\frac{V}{K_V}\right)^n}{1 + \left(\frac{U}{K_U}\right)^n + \left(\frac{V}{K_V}\right)^n} \quad (5)$$

where U and V are two odors (and also their concentrations), n is a Hill coefficient, K_U , K_V , F_{MU} , and F_{MV} are constants depending on the receptor kinetic properties.

In particular, for the dose-response function to single odor F_U , the Hill coefficient n modulates the steepness of the curve, K_U the midpoint, and F_{MU} the asymptotic value.

As it is usual to keep unchanged the quality of the odor in a binary mixture under a change of its concentration, it suffices that the ratio of concentrations of the two odor components remains constant (Rospars 2013). In other classical protocols, as in Cruz and Lowe (2013), the concentration of a single component is varied while that of the other remains constant. In the first case, it has been widely demonstrated that the response can be conveniently reproduced by a logistic curve as a function of concentration $U + V$. Then, in Rospars et al. (2008) is proved that if $U = rV$, where r is a positive constant, Eq. 5₂ becomes

$$F_{U+V}(M) = \frac{F_{Mp}}{1 + \left(\frac{K_p}{M}\right)^n}, \quad (6)$$

where $M = U + V$, and

$$F_{Mp} = \frac{F_{MU} r^n K_V^n + F_{MV} K_U^n}{(K_U^n + r^n K_V^n)},$$

$$K_p = (1 + r) K_U K_V \sqrt[n]{\frac{1}{r^n K_V^n + K_U^n}}. \quad (7)$$

Therefore, F_{Mp} is the asymptotic value of function $F_{U+V}(M)$, and the concentration of M at half maximum response $F_{Mp}/2$ is K_p .

To test the model, the authors fitted the experimental data on the response to single odors determining the parameters n , common to both odors, the midpoints K_U and K_V , and the asymptotic values F_{MU} and F_{MV} . Then, using Eqs. 6 and 7 each dose-response curve for binary mixtures was determined. Finally, the predicted responses were compared to their observed counterparts (see Rospars (2013), Figs. 6–7). In 47% of comparisons, the Hill curve fitted to the experimental data was statistically undistinguishable from those predicted by the model. In these cases, it can be assumed that the odorant-OR interactions were competition, or at least that the effects of a different nature were too weak to reach statistical significance (see Rospars (2013), Fig. 6). In the other half, the shifts of curves along the concentration axis (*affinity modification*) and the changes of maximal responses (*efficiency modification*) with respect to model predictions indicate that noncompetitive interactions, like antagonism and allosterism, occur (see Rospars (2013), Fig. 7).

This approach is able to explain all cases of suppression, but it cannot reproduce mixtures exhibiting synergy, and inhibition, at least in the region of the maximum response (Rospars 2013, Fig. 7). In fact, from Eq. 7 for all r we obtain

$$\min(F_{MU}, F_{MV}) \leq F_{Mp} \leq \max(F_{MU}, F_{MV}), \quad (8)$$

i.e., the asymptotic value of function F_{U+V} is always located between the single-odorant curves.

Finally, it has also been noted (Cruz and Lowe 2013) that it cannot take into account the self-mixture case, i.e., it should be $F_{U+U}(U, U) = F_{U+U}(2U, 0)$.

Cruz and Lowe Models

In Cruz and Lowe (2013), instead of Eqs. 5 and 6, it was proposed to use for single odors and binary mixture the following (empirical) models

$$F_U = \frac{F_{\max}}{1 + \frac{1}{\eta_U} \left(1 + \frac{K_U}{U}\right)^n}, \quad (9)$$

$$F_{U+V}(U, V) = \frac{F_{\max}}{1 + \left[\frac{1 + \frac{U}{K_U} + \frac{V}{K_V}}{\eta_U \frac{U}{K_U} + \eta_V \frac{V}{K_V}} \right]^n},$$

where n is a Hill coefficient, $F_{\max}$ is the maximal response, and η_U and η_V are the efficiencies of activation of transduction by each odorant.

Differently from Rospars et al. (2008), the introduction of the new parameter η offers the possibility to use the same $F_{\max}$ for all odors while allowing different asymptotes. For example, if we consider the model for single odors Eq. 9₁, the asymptotic value of function F_U writes

$$\text{asy}_U = \frac{F_{\max}}{1 + \frac{1}{\eta_U}}. \quad (10)$$

As with the model of Rospars et al., if the concentrations U and V of the odorants are such that $U = rV$, Eq. 9₂ becomes a Hill function

$$F_{U+V}(M) = \frac{F_{\max}}{1 + \frac{1}{\bar{\eta}} \left(1 + \frac{\bar{K}}{M}\right)^n} \quad (11)$$

where the parameters $\bar{\eta} = \bar{\eta}(r, \eta_U, \eta_V, K_U, K_V)$ and $\bar{K} = \bar{K}(r, K_U, K_V)$ assume the form

$$\bar{\eta} = \frac{\eta_U r K_V + \eta_V K_U}{K_U + r K_V}, \quad \bar{K} = \frac{(r+1)K_U K_V}{K_U + r K_V}. \quad (12)$$

In this case, the asymptotic value of function $F_{U+V}(M)$ is

$$\text{asy}_M = \frac{F_{\max}}{1 + \frac{1}{\bar{\eta}}}, \quad (13)$$

and the concentration of M at half maximum response $\frac{F_{\max}}{2(1 + \frac{1}{\bar{\eta}})}$ is

$$\text{EC}_{50} = \frac{\bar{K}}{\sqrt[2]{2 + \bar{\eta}} - 1}.$$

From Eq. 12 we obtain

$$\min(\eta_U, \eta_V) \leq \bar{\eta} \leq m \max(\eta_U, \eta_V)$$

and owing to Eq. 13 for all r we have

$$\min \left(\frac{F_{\max}}{1 + \frac{1}{\eta_U^n}}, \frac{F_{\max}}{1 + \frac{1}{\eta_V^n}} \right) \times \leq \frac{F_{\max}}{1 + \frac{1}{\bar{\eta}^n}} \leq \max \left(\frac{F_{\max}}{1 + \frac{1}{\eta_U^n}}, \frac{F_{\max}}{1 + \frac{1}{\eta_V^n}} \right). \quad (14)$$

Although this model is consistent with the self-mixture case, due to Eq. 14 the model cannot reproduce mixtures exhibiting synergy or inhibition in their maximal response.

Contrary to Rospars et al. (2008), in Cruz and Lowe (2013) the binary mixtures are tested at a fixed concentration of one of the components, and the model (9)₂ represents the glomerular dose responses. As we see in Fig. 3, the model is consistent with the mixture responses of *moderate sensitivity glomeruli* (Cruz and Lowe 2013). We remark that in Cruz and Lowe (2013) is assumed

that in a binary mixture the odorants compete for the same receptor binding site in the population of OSNs projecting to a given glomerulus. Although each odorant have its own independent binding affinity K and efficiency of transduction activation η , a common Hill coefficient n still describes cooperativity of the shared transduction cascade as well as the upper limit $F_{\max}$ of the response with transduction fully activated. Nevertheless, the glomerular dose-responses curves for binary mixtures of the odorants EG (eugenol) and MIEG (methyl isoeugenol) in Fig. 3, although refer to the same glomerulus, exhibit different values for all parameters. This indicates that the experiments were (probably) carried out on different OSNs even though the dose-response functions refer to the same glomerulus.

Marasco et al. Models

The major problem with Rospars et al. (2008) and Cruz and Lowe (2013) approaches is that these models are able to reproduce all cases of suppression, but they cannot reproduce (binary) mixtures exhibiting synergy, and inhibition, at least in the region of the maximum response (see Eqs. 8 and 14). To determine a model able to describe each type of interaction among two or more odorants

Olfactory Sensory Neurons to Odor Stimuli: Mathematical Modeling of the Response, Fig. 3 Glomerular dose responses. (a) $F_{\max} = 2.01$, $K_{EG} = 0.49$, $K_{MIEG} = 1.04$,

$n = 4.17$, $\eta_{EG} = 1.63$, $\eta_{MIEG} = 2.18$; (b) $F_{\max} = 2.12$, $K_{EG} = 0.71$, $K_{MIEG} = 1.13$, $n = 4.47$, $\eta_{EG} = 1.45$, $\eta_{MIEG} = 2.01$

(see Fig. 2 for a binary mixture), it is necessary to expand the space of allowed Hill functions. Then, assuming that the Hill coefficient in the mixture model (9)₂ depends on the odorants U and V , Marasco et al. (2016) proposed to describe the dose-response functions for a given type of OSNs in the presence of single odor and mixtures as follows:

$$F_U(U) = \frac{F_{\max}}{1 + \frac{1}{\eta_U} \left(1 + \frac{K_U}{U}\right)^{n_U}}, \quad (15)$$

$$F_{U+V}(U, V) = \frac{F_{\max}}{1 + \left[\frac{1 + \frac{U}{K_U} + \frac{V}{K_V}}{\eta_U K_U + \eta_V K_V} \right]^{n_{U+V}}},$$

where

$$n_{U+V} = \frac{n_U \eta_U K_V U + n_V \eta_V K_U V}{\eta_U K_V U + \eta_V K_U V}. \quad (16)$$

Moreover, Eq. 15₂ can be easily generalized to a model for a mixture of $N \geq 2$ odorants as follows:

$$F_{MIX}(U_1, \dots, U_N) = \frac{F_{\max}}{1 + \left[\frac{1 + \sum_{i=1}^N \frac{U_i}{K_{U_i}}}{\sum_{i=1}^N \eta_{U_i} \frac{U_i}{K_{U_i}}} \right]^{n_{MIX}}} \quad (17)$$

where

$$n_{MIX} = \frac{\sum_{i=1}^N n_{U_i} \eta_{U_i} \frac{U_i}{K_{U_i}}}{\sum_{i=1}^N \eta_{U_i} \frac{U_i}{K_{U_i}}}. \quad (18)$$

If $U = rV$ where r is a positive constant, Eq. 15₂ becomes

$$F_{U+V}(M) = \frac{F_{\max}}{\left\{1 + \frac{1}{\bar{\eta}} \left(1 + \frac{\bar{K}}{M}\right)^{\bar{n}}\right\}}, \quad (19)$$

where the parameters $\bar{\eta} = \bar{\eta}(r, \eta_U, \eta_V, K_U, K_V)$, $\bar{K} = \bar{K}(r, K_U, K_V)$ and $\bar{n} = \bar{n}(r, n_U, n_V, \eta_U, \eta_V, K_U, K_V)$ assume the form

$$\begin{aligned} \bar{\eta} &= \frac{\eta_U r K_V + \eta_V K_U}{K_U + r K_V}, \\ \bar{K} &= \frac{(1+r) K_U K_V}{K_U + r K_V}, \\ \bar{n} &= \frac{r n_U \eta_U K_V + n_V \eta_V K_U}{r \eta_U K_V + \eta_V K_U}. \end{aligned} \quad (20)$$

Similarly, setting for all $i \in \{1, \dots, N-1\}$, $U_i = r_i U_N$ where r_i are positive constants, and $M = \sum_{i=1}^N U_i$ we obtain

$$F_{MIX}(M) = \frac{F_{\max}}{1 + \frac{1}{\eta_{MIX}} \left(1 + \frac{K_{MIX}}{M}\right)^{n_{MIX}}} \quad (21)$$

where

$$\begin{aligned} \eta_{MIX} &= \frac{\sum_{i=1}^{N-1} \frac{r_i}{K_{U_i}} \eta_{U_i} + \frac{1}{K_{U_N}} \eta_{U_N}}{\sum_{i=1}^{N-1} \frac{r_i}{K_{U_i}} + \frac{1}{K_{U_N}}}, \\ K_{MIX} &= \frac{\left(1 + \sum_{i=1}^{N-1} r_i\right)}{\sum_{i=1}^{N-1} \frac{r_i}{K_{U_i}} + \frac{1}{K_{U_N}}}, \\ n_{MIX} &= \frac{\sum_{i=1}^{N-1} n_{U_i} \eta_{U_i} \frac{r_i}{K_{U_i}} + n_{U_N} \eta_{U_N} \frac{1}{K_{U_N}}}{\sum_{i=1}^{N-1} n_{U_i} \frac{r_i}{K_{U_i}} + n_{U_N} \frac{1}{K_{U_N}}}. \end{aligned} \quad (22)$$

The asymptotic values of the functions (19) and (21) are

$$\text{asy}_M = \frac{F_{\max}}{1 + \frac{1}{\bar{\eta}}}, \quad \text{asy}_{M_{MIX}} = \frac{F_{\max}}{1 + \frac{1}{\eta_{MIX} n_{MIX}}}, \quad (23)$$

and the concentrations of M at half maximum response are

$$\begin{aligned} \text{EC}_{50} &= \frac{\bar{K}}{\sqrt[n]{2 + \frac{1}{\bar{\eta}} - 1}}, \\ \text{EC}_{50_{MIX}} &= \frac{K_{MIX}}{n_{MIX} \sqrt[n]{2 + \frac{1}{\eta_{MIX} n_{MIX}} - 1}}. \end{aligned} \quad (24)$$

It should be noted that if $n_U = n_V$, then Marasco et al. binary mixture models (15)₂ and (19) reduce

to those proposed in Cruz and Lowe (2013), i.e., models (9)₂ and (11), respectively.

The model (15)₂ can take into account all types of interaction between odors in a binary mixture as reported in Fig. 2. Moreover, since all the experimentally measurable characteristics of the curve for the mixture (i.e., steepness, asymptotic value, and midpoint) can be expressed by a non-linear combination of the parameters for the individual components, it is thus possible to find mathematical conditions for all parameters and concentrations to design mixtures with specific properties (Marasco et al. (2016), Appendix A.3 and Figs. 2–3). In particular, it is mathematically demonstrated that synergy cannot be obtained for concentration values below the midpoint of the component with the lower Hill coefficient (Marasco et al. (2016), Appendix A.3).

The binary mixture model (15)₂ is validated through three set of experimental data obtained using different protocols (Rospars et al. 2008;

Cruz and Lowe 2013; Duchamp-Viret et al. 2003). In almost all cases, it is obtained a very good qualitative and quantitative agreement with experimental data (see Fig. 4, and (Marasco et al. (2016), Appendix A.4 and Tables S2–S3)).

In particular, the first four panels of Fig. 4 demonstrate that the model is able to correctly reproduce suppression (Fig. 4, top left), hypo-additivity (Fig. 4, top center), and inhibition (Fig. 4, top right and bottom left). The bottom central and right panels of Fig. 4 refer to binary mixtures as a function of the concentration of one odor (EG) with a second odor added at a fixed concentration (MIEG). Also in this case the model was in very good agreement with experiments over the entire concentration range that was tested. To confirm these results both the average square error (MSE) and the absolute percentage error (MAPE) have been used to quantitatively compare the experimental data with the predicted data (Marasco et al. (2016), Appendix A.4 and

Olfactory Sensory Neurons to Odor Stimuli: Mathematical Modeling of the Response, Fig. 4 Model validation against experimental findings. In each panel are reported the experimental responses recorded in an OSN to two single odors (black and red symbols) and to their

mixture at the same dilution (blue symbols) as a function of the odor concentration. Black and red lines represent best fits of experimental points, according to Eq. 15₁. The blue line in each panel represents the model prediction for the mixture using Eqs. 19 and 15₂

Olfactory Sensory Neurons to Odor Stimuli: Mathematical Modeling of the Response, Fig. 5 The odor response space can be generated by a three vector basis. (left panel) The sets $B_1 = \{(n_{\min}, \eta_{\max}, s_2), (n_{\max}, \eta_{\min}, s_3), (n_{\max}, \eta_{\max}, s_4)\}$, and $B_2 = \{(n_{\min}, \eta_{\min}, s_1), (n_{\min}, \eta_{\max}, s_2)\}$,

$(n_{\max}, \eta_{\min}, s_3)\}$ cover every odorant $F_{(n,\eta,s)}$ in the cyan and pink area, respectively. (right panel) Any target odor O_R can be obtained as a mixture of odors in a mathematically predictable manner

Tables S2–S3). There are three cases in which the model failed to reproduce experimental findings (Marasco et al. 2016, Fig. 5). The possible reasons for this discrepancy could be due to both a model limitation and to the way in which the experimental results for the mixture are determined and represented in Rospars et al. (2008) and Duchamp-Viret et al. (2003).

The Mathematical Structure of the Odor Response Space (ORS)

In this section, the mathematical structure of the odor response space (ORS) introduced in Marasco et al. (2016) and its consequences are analyzed.

In color vision, it has been found a set of “primary colors” that can be combined in varying amounts to produce a range of colors belonging to the color perception space. On the contrary, the possibility to express the response of olfactory sensory neurons (OSNs) to odor stimuli in terms of a few elementary and objective responses, i.e., the “primary odor responses”, remains still open.

In Marasco et al. (2016), using experimental constraints and provided that any OSN response curve can be represented as a Hill function of the odor concentration, it is demonstrated that the odor response space is three-

dimensional, and the dose-response function of any odor receptor can be obtained from three (out of four) primary components with specific properties.

Let us consider the function

$$F_{(n,\eta,s)}(X) = \frac{F_{\max}}{1 + \left(\frac{1+sX}{\eta s X}\right)^n}, \quad (25)$$

where the variable X ranges in the real positive numbers, and the parameters n, η, s are positive as well. Note that when $s = 1/K$ and X is an odorant concentration ($U, V, M, \dots$), we get Eqs. 15₁, 19, or 21. In this way OSN responses are univocally identified by the triples (n, η, s) and the **odor response space** writes

$$ORS = \left\{ \frac{F_{\max}}{1 + \left(\frac{1+sX}{\eta s X}\right)^n} \right\}_{n,\eta,s \in \mathbb{R}^+}. \quad (26)$$

Let us introduce two **composition laws**

$$(n, \eta, s) \times \bullet (n', \eta', s') = \left(\frac{n\eta s + n'\eta' s'}{\eta s + \eta' s'}, \frac{\eta s + \eta' s'}{s + s'}, s + s' \right),$$

$$\alpha \ast (n, \eta, s) = (n, \eta, \alpha s), \alpha \in \mathbb{R}_+, \quad (27)$$

where $(n, \eta, s) \bullet (n', \eta', s')$ identifies a mixture of two odorants (n, η, s) and (n', η', s') , i.e.,

$$(n, \eta, s) \bullet (n', \eta', s') \leftrightarrow F_{(n, \eta, s) \bullet (n', \eta', s')} = \frac{F_{\max}}{1 + \left(\frac{1 + (s + s')X}{(\eta s + \eta' s')X} \right)^{\frac{\eta \eta s + \eta' \eta' s'}{\eta s + \eta' s'}}$$

$\alpha \times (n, \eta, s)$, $\alpha \in \mathbb{R}_+$ identifies the odorant (n, η, s) at concentration αX , i.e.,

$$\alpha \times (n, \eta, s) \leftrightarrow F_{\alpha \times (n, \eta, s)} = \frac{F_{\max}}{1 + \left(\frac{1 + s(\alpha X)}{\eta s(\alpha X)} \right)^n}.$$

Owing to Eq. 27, to mix odorants (n, η, s) , (n', η', s') at a fixed ratio r ($U = rV$) is equivalent to consider the following combination

$$\left[\frac{r}{r+1} \times (n, \eta, s) \right] \bullet \left[\frac{1}{r+1} \times (n', \eta', s') \right].$$

The operation $\bullet$ is commutative and associative, i.e., a mixture of several odorants does not depend on the way one mixes them but only on the reciprocal ratios. On the other hand, we cannot have “opposite odorants”, because of the positivity constraints of the parameters (n, η, s) . This prevents the operations (27) from defining a vector space structure; in fact the odor space can be mapped only on the positive octant $\mathbb{R}_+^3$

$$(ORS, \bullet, \times) \mapsto (\mathbb{R}_+^3, +, \cdot)$$

by means of the application

$$(n, \eta, s) \mapsto (n\eta s, \eta s, s), \quad (28)$$

from which we obtain that

$$\begin{aligned} (n, \eta, s) \bullet (n', \eta', s') &\mapsto (n\eta s, \eta s, s) + (n' \eta' s', \eta' s', s'), \\ \alpha \times (n, \eta, s) &\mapsto \alpha(n\eta s, \eta s, s). \end{aligned} \quad (29)$$

As in $\mathbb{R}^3$ three independent vectors (i.e., a basis) suffice to generate the whole space, also in ORS , under the appropriate constraints, any odor response

can be represented by a combination of three primary responses. In detail, choosing a basis in $\mathbb{R}_+^3$

$$\begin{aligned} \mathbf{e}_1 &= (n_1 \eta_1 s_1, \eta_1 s_1, s_1), \\ \mathbf{e}_2 &= (n_2 \eta_2 s_2, \eta_2 s_2, s_2), \\ \mathbf{e}_3 &= (n_3 \eta_3 s_3, \eta_3 s_3, s_3), \end{aligned} \quad (30)$$

every vector $(n\eta s, \eta s, s) \in \mathbb{R}_+^3$ is uniquely obtained as a linear combination of Eq. 30, i.e.,

$$\begin{aligned} \forall (n\eta s, \eta s, s) \exists! (\alpha_1, \alpha_2, \alpha_3) : \\ (n\eta s, \eta s, s) = \sum_{i=1}^3 \alpha_i (n_i \eta_i s_i, \eta_i s_i, s_i), \end{aligned} \quad (31)$$

where the scalars $\alpha_1, \alpha_2, \alpha_3$ must be positive and fulfilling some mathematical constraints (Marasco et al. (2016), Appendix A.5).

From Eq. 29 we have

$$\begin{aligned} [\alpha_1 \times (n_1, \eta_1, s_1)] \bullet [\alpha_2 \times (n_2, \eta_2, s_2)] \\ \bullet [\alpha_3 \times (n_3, \eta_3, s_3)] \mapsto \sum_{i=1}^3 \alpha_i (n_i \eta_i s_i, \eta_i s_i, s_i), \end{aligned} \quad (32)$$

hence an odorant $(n, \eta, s) \in ORS$ is a combination of three **primary responses**

$$\begin{aligned} F_{(n_1, \eta_1, s_1)} &= \frac{F_{\max}}{1 + \left(\frac{1 + s_1 X}{\eta_1 s_1 X} \right)^{n_1}}, \\ F_{(n_2, \eta_2, s_2)} &= \frac{F_{\max}}{1 + \left(\frac{1 + s_2 X}{\eta_2 s_2 X} \right)^{n_2}}, \\ F_{(n_3, \eta_3, s_3)} &= \frac{F_{\max}}{1 + \left(\frac{1 + s_3 X}{\eta_3 s_3 X} \right)^{n_3}}, \end{aligned}$$

by means of positive scalars $\alpha_1, \alpha_2, \alpha_3$, fulfilling some mathematical constraints (Marasco et al. (2016), Appendix A.5). Due to these restrictions, no triple can cover the whole space, i.e., a basis formed by a triple cannot generate all possible responses. However, if we suppose that odorant parameters (n, η, s) are (experimentally) constrained as follows

$$n \in [n_{\min}, n_{\max}], \eta \in [\eta_{\min}, \eta_{\max}], s > 0, \quad (33)$$

then, the convex hull given by the four vertices

$$\begin{aligned}
 (n_{\min}, \eta_{\min}, s_1), s_1 > 0, (n_{\min}, \eta_{\max}, s_2), s_2 > 0, \\
 (n_{\max}, \eta_{\min}, s_3), s_3 > 0, (n_{\max}, \eta_{\max}, s_4), s_4 > 0,
 \end{aligned}
 \quad (34)$$

covers every odorant $F_{(n,\eta,s)}$ verifying Eq. 33 (see Fig. 5 (left panel), and (Marasco et al. (2016), Appendix A.5).

To illustrate practical consequences of this approach, the authors consider the problem of synthesizing a target odor, O_R , smelling let's say as a rose. This would be represented by the set of OSN responses that can be considered essential to smell a rose ($G_{1R}, \dots, G_{4R}$, blue symbols in Fig. 5 (right panel)). Then, the analysis predicts that it could be conveniently obtained with a mixture of odors activating the same OSNs (red and black symbols in Fig. 5 (right panel)) combined with coefficients that can be mathematically determined (Marasco et al. (2016), Appendix A.6).

Olivocerebellar Pathway

Martin Garwicz

Department of Experimental Medical Science,
Neuronano Research Center, Lund University,
Lund, Sweden

Definition

The olivocerebellar pathway originates in the inferior olive in the brain stem, projects to the cerebellar cortex, and terminates as climbing fibers on the dendrites of the cerebellar cortical Purkinje cells.

Detailed Description

Cerebellar Function and Information Processing

The cerebellum is involved in a wide range of processes, including cognitive functions (Thach 1996; Schmähmann 1997, 2010), but is best known for its pivotal role in the control of movement. This role is usually described as regulatory,

as the cerebellum is in principle not essential for initiation or execution of movements. Rather, cerebellar deficits result in a lack of coordination (Babinski 1899, 1906; Holmes 1917, 1939; Chambers and Sprague 1955; Dow and Moruzzi 1958; Ito 1984).

The regions of the cerebellum that are related to motor control receive a wide variety of sensory inputs and generate motor-related outputs according to internal rules of computation. These rules are determined by the connectivity of cerebellar cortical neurons and their intrinsic properties. Hence, the computational constraints on the information processing underlying cerebellar function are to a high degree determined by the information content of inputs to the cerebellum together with the structural organization of its internal circuitry.

The Olivocerebellar Pathway

The olivocerebellar pathway constitutes one of the principal inputs to the cerebellum and is considered a key determinant of cerebellar functional organization and of its mode of operation (Oscarsson 1980). The inferior olive is the only source of cerebellar climbing fibers, and the integrity of the inferior olive and the olivocerebellar pathway is crucial for cerebellar function (Oscarsson 1980; Voogd and Bigaré 1980).

Motor learning and motor adaptation are considered salient features of the cerebellar mode of operation (Ito et al. 1974; Robinson 1976; Thach 1998), and the long-term synaptic plasticity underlying these phenomena is fundamental to the information processing of cerebellar neuronal networks (Ekerot and Kano 1985; Ito 1989, 2001; Hansel et al. 2001). Climbing fiber input is thought to be instrumental in the induction of cerebellar synaptic plasticity in the context of motor learning and motor adaptation (Gilbert and Thach 1977). Impulses in the climbing fibers generate the largest depolarizing event observed in any neuron, a highly characteristic burst of potentials usually referred to as a “complex spike” (Gilbert and Thach 1977; Simpson et al. 1996).

Cerebellar Organization: Olivocerebellar Zones and Microzones

Different subdivisions of the inferior olive project to different regions of the cerebellar cortex and serve different functions (Oscarsson 1980; Voogd and Bigaré 1980). Modern accounts of cerebellar functional organization emphasize its high degree of compartmentalization, with a division of the cerebellar cortex into a number of sagittal zones as organizing principle (Oscarsson 1979). Individual zones are typically 1–2 mm wide and characterized by their specific olivocerebellar and corticonuclear connectivity (Fig. 1a, top panel) (Oscarsson 1979, 1980; Voogd and Bigaré 1980).

Within each zone, smaller units – “microzones” – can be identified by electrophysiological means and are defined by the specific characteristics of their climbing fiber input (Andersson and Oscarsson 1978; Oscarsson 1979; Ekerot et al. 1991). A microzone is a narrow longitudinal strip of cerebellar cortex within which all Purkinje cells receive climbing fiber input from highly similar receptive fields. Microzones with similar characteristics but located in different sagittal zones are the defining components of multi-zonal (olivo–corticonuclear) “microcomplexes” (Fig. 1a) (Garwicz 2002; Apps and Garwicz 2005). These may be thought of as fundamental processing units and the cerebellar counterparts of cerebral cortical columns.

Spino–Olivocerebellar Relationships

The most extensively studied subdivisions of the inferior olive and the corresponding cerebellar cortical zones are related to various aspects of motor control, such as the vestibuloocular reflex or voluntary limb movements (Ito 2013). As regards limb movement control, the intricate interconnectivity between spinal cord withdrawal reflex circuitry and the olivocerebellar pathway to which it connects has been particularly well characterized with respect to information content (Fig. 1a and b) (Garwicz 2002; Apps and Garwicz 2005).

In brief, olivocerebellar climbing fibers projecting to the cerebellar zones controlling

Olivocerebellar Pathway, Fig. 1 Spino–olivocerebellar connectivity. Functional interrelationships between spinal withdrawal reflex circuits and cerebellar multi-zonal microcomplexes controlling the rubrospinal and

corticospinal tracts (the latter not shown). (a) *Upper panel* shows dorsal view of cat cerebellum, with the forelimb-related areas of sagittal zones C1, C3, and Y schematically indicated by green on the cerebellar

rubrospinal and corticospinal tracts monitor the activity of individual withdrawal reflex modules acting upon single limb muscles (Garwicz et al. 2002). Although it was postulated already in the early 1970s that the olivocerebellar climbing fibers may convey information about the activity in “lower motor centers” (Oscarsson 1973), it was not until 30 years later that more direct evidence was obtained to support this notion (Garwicz et al. 2002).

Encoding of Sensorimotor Information in the Olivocerebellar Pathway

The detailed spatial encoding of sensory information mediated by the olivocerebellar pathway shows that an individual olivocerebellar climbing fiber afferent conveys information representing the skin area that is moved when a specific single limb muscle contracts (Fig. 1b, right panel). The distribution of response amplitudes or sensitivity to stimulation within this skin area reflects in great detail the withdrawal efficacy of the muscle (Fig. 1b, left panel) (Schouenborg and Kalliomäki 1990; Schouenborg and Weng 1994). Notably, the biomechanics are adapted to a standing limb position, with the distal limb segment in touch with and supported by the underlying surface.

In addition, the same climbing fiber receives input from group II muscle afferents, originating mainly in the same muscle (Fig. 1a, bottom panel) (Jörmell et al. 1996; Garwicz et al. 2002). Therefore, an individual climbing fiber monitors both

the input and the output elements of an individual spinal withdrawal reflex module. This convergence emphasizes the integrated sensorimotor nature of the information conveyed by the olivocerebellar climbing fibers and indicates that climbing fiber signals that arise from the spinal cord might be pre-processed by spinal withdrawal reflex circuits (Garwicz 2002; Apps and Garwicz 2005).

Input–Output Relationships of Olivo–Corticonuclear Processing Units

A multi-zonal (olivo–corticonuclear) microcomplex (MZMC) typically controls a muscle synergy acting across several limb segments (Ekerot et al. 1995). The distal-most muscle in the muscle synergy seems to have a roughly antagonistic action to the muscle associated with the input side of the circuit (Fig. 1a, bottom left). For instance, an MZMC receiving its climbing fiber input from the withdrawal reflex that activates a palmar flexor of the wrist has a receptive field that has as its center an area of skin on the ventral forepaw just proximal to the central footpad. When the limb is in a standing position, the action of this muscle is to withdraw this particular area of skin away from the stimulus. By contrast, the muscle synergy that constitutes the output from this specific MZMC seems to include the approximate antagonist of this muscle, which is a dorsal flexor of the wrist (Ekerot et al. 1995; Garwicz 2002; Apps and Garwicz 2005).

Olivocerebellar Pathway, Fig. 1 (continued) surface. Purkinje cells represent microzones with similar climbing fiber input, mediated via the olivocerebellar pathway. *Lower panel* shows the organization of spinal circuitry related to the withdrawal reflex module acting on the palmaris longus muscle. Reflex output from spinal cord to palmaris longus indicated by *light green*; reflex input from the skin (*dark green*) and from the muscle itself (*yellow*). The spinal interneuron (*light green*) is shown to project both to reflex output motor neuron and to the inferior olive, the origin of the olivocerebellar pathway.

The cerebellar output from the same multi-zonal (olivo–corticonuclear) microcomplex, mediated via the rubrospinal tract, is shown schematically in red. Note that the main output from the microcomplex is to the antagonist of the muscle that constitutes the output of the associated spinal withdrawal reflex module. **(b)** The distribution of sensitivity within the receptive field on the skin (*right panel*) corresponds in detail to the withdrawal efficacy of the muscle (*left panel*) when the limb is in the standing position, i.e., acting against a surface

Open Source Brain

Padraig Gleeson, R. Angus Silver and Matteo Cantarelli
Department of Neuroscience, Physiology and Pharmacology, University College London, London, UK

Definition

Open Source Brain (<http://www.opensourcebrain.org>) is an online repository of computational models of ion channels, synapses, neurons, simple network models, and more detailed three-dimensional models of neuronal microcircuits from multiple brain regions and species. It is intended to facilitate sharing and collaborative

Open Source Brain, Fig. 1 The interface for browsing the cell and network models on OSB

development of neuronal models by researchers around the world.

Detailed Description

The ever-increasing complexity of models and applications used in computational neuroscience makes it clear that no one researcher or lab can implement and maintain detailed models which are applicable to a broad range of research questions and can be used across the diverse applications available for simulation and analysis. A more collaborative approach to neuronal model development, inspired by the success of the open source software movement, is required (Davison 2012). The Open Source Brain repository (OSB, <http://www.opensourcebrain.org>) is being developed to enable researchers to collaboratively develop

computational models of cells and networks which are well tested and documented and can be run across multiple simulators. This is enabled through the use of advanced distributed version control technologies (<http://www.github.com>) and by converting the models to open, standardized formats like NeuroML (Gleeson et al. 2010), allowing the models to be used by the increasing range of simulators and other applications in the NeuroML “ecosystem” (http://www.neuroml.org/tool_support.php). Models can also be specified in the cross-simulator Python-based PyNN language (Davison et al. 2008). Greater interoperability underdevelopment between NeuroML and PyNN means that a wide range of neuronal model types, from large-scale point neuron models to morphologically and biophysically detailed three-dimensional network models, is supported by OSB.

Open Source Brain, Fig. 2 Using the OSB 3D Explorer to visualize the *C. elegans* connectome as developed by the OpenWorm project

The current version of OSB contains models from diverse brain regions including the neocortex, cerebellum, and hippocampus; invertebrate models; as well as more abstract cell and network models (Fig. 1). OSB complements existing model archives (e.g., ModelDB) which have traditionally concentrated on providing snapshots of already published models. The cell, ion channel, synapse, and network models in OSB develop over time to ensure they reflect known physiology and best practices in modeling. Users can comment on/extend/debug any other model as well as contribute their own. Many of the projects on OSB include support for neuroConstruct (Gleeson et al. 2007), a graphical tool which facilitates running a local copy of the model in a number of supported neuronal simulation environments, including NEURON, GENESIS, and MOOSE.

A major recent addition to the functionality of OSB is the 3D Explorer, allowing cells and networks in NeuroML version 2.0 format to be viewed inside the browser (using WebGL and so requiring no additional software to be installed) and their structure and physiological properties examined (Fig. 2). This means modelers need only commit models in NeuroML 2 format to a project repository (e.g., on GitHub) to have access to this advanced feature.

As well as providing cell and network models from specific brain regions, OSB contains a number of “Technology Showcase” projects, with the aim of illustrating how OSB can interact with other specialist neuroinformatic resources and tools. These include NeuroMorpho, which provides neuronal reconstructions in multiple formats including NeuroML; NeuroElectro, which provides structured data on electrophysiological properties of identified neurons which can be used to test the behavior of OSB models; and Virtual Fly Brain, which provides detailed information on *Drosophila* neurons and brain regions. Close links with other initiatives including NIF/NeuroLex (<https://www.neuinfo.org>) and the OpenWorm project (<http://openworm.org>) are also being developed.

This work has been primarily funded by the Wellcome Trust (086699/095667).

Optic Flow Fields

► Optic Flow Processing

Optic Flow Processing

Holger G. Krapp

Department of Bioengineering, Imperial College London, London, UK

Synonyms

Directional motion; Matched filters; Motion parallax; Optic flow fields; Optical flow; Relative motion; Velocity vector fields

Definition

Optic flow describes the geometrical projection of relative motion between the visual environment and a moving optical system. It is commonly formalized by a distribution of local velocity vectors, observed at many different positions within the optical system’s visual field. Together, the local velocity vectors constitute a pattern of coherent image motion called an optic flow field. The

direction and magnitude of the velocity vectors depend on the instantaneous self-motion of the optical system which may be decomposed into its translation and rotation components. The magnitude of translation-induced contribution to a given velocity vector depends on the distance between the optical system and objects within the visual field, while the rotation-induced contribution is distance invariant. Given its properties, optic flow contains a significant amount of information about the self-motion and relative distance information that can be exploited for guidance and control tasks.

Detailed Description

The intimate relationship between self-motion and specific patterns of image motion was noticed early on by J. J. Gibson in the mid-twentieth century. In his book *The Perception of the Visual World* (1950) and later in *The Ecological Approach to Visual Perception* (1979), Gibson mainly focused on qualitative properties of optic flow. But it was undoubtedly his work that provided the conceptual foundation for later quantitative approaches on how optic flow may be exploited to estimate self-motion, which were mainly driven by computer vision and visual neuroscience. The first mathematical descriptions of optic flow fields became available in the mid-1970s (e.g., Nakayama and Loomis 1974; Koenderink and van Doorn 1975) and 1980s (e.g., Horn and Schunck 1981). From then on, researchers in computer vision, natural sciences, and engineering started to take advantage of the formal relationship between the self-motion components of optical systems – either eyes or cameras – and the resulting optic flow fields (e.g., Barron et al. 1994).

Movements in Space

Any movement in space may be described as a combination of translation and rotation, conveniently parameterized as the projections of their components onto the cardinal axes of a Cartesian

coordinate system that has its origin in the center of the optical system. The components are often referred to as thrust, slideslip, and lift in terms of translations along the x-, y-, and z-axis, respectively, while rotations around these axes are called roll, pitch, and yaw (Fig. 1). Together, the projections onto the cardinal axes define the translation vector, $\mathbf{T} = [T_x, T_y, T_z]^T$, and the rotation vector, $\mathbf{R} = [R_x, R_y, R_z]^T$, which results in 6 degrees of freedom, where the superscript T denotes the transpose of a vector.

Local Image Shifts Quantified as Parallax Vectors

From the center of the coordinate system, the lines of sight to any given points in a spherical visual field may be described by direction vectors $\mathbf{d}_i$, where the index i ($= 1, 2, \dots, N$) refers to the number of different points observed. During self-motion, the observed points in the visual field change their location over time relative to the optical system depending on where they are observed and what the self-motion components $\mathbf{T}$ and $\mathbf{R}$ of the optical system are. The resulting image shifts of the observed points are equivalent to the temporal derivative of the direction vectors, $\mathbf{d}_i$, and are described as local parallax vectors, $\mathbf{p}_i$, according to a basic vector equation. Using the notation proposed by Koenderink and van Doorn (1987), each local parallax vector, $\mathbf{p}_i$, is defined as.

$$\mathbf{p}_i = \frac{\partial \mathbf{d}_i}{\partial t} = -(\mathbf{T} - (\mathbf{T} \cdot \mathbf{d}_i)\mathbf{d}_i)/D_i - (\mathbf{R} \times \mathbf{d}_i), \quad (1)$$

where $\mathbf{T}$ denotes the translation vector, D_i gives the distances of the observed points along directions $\mathbf{d}_i$, and $\mathbf{R}$ is the rotation vector. The expression $(\mathbf{T} \cdot \mathbf{d}_i)$ on the right-hand side of Eq. 1 gives the dot (scalar) product between the translation vector and the direction vectors $\mathbf{d}_i$, and the operator $\times$ symbolizes the cross product, here calculated between the rotation vector and the observation directions $(\mathbf{R} \times \mathbf{d}_i)$.

To gain some intuition on how self-motion components and parallax vectors are related to one

Optic Flow Processing, Fig. 1 Self-motion components in a Cartesian coordinate system. (a): Self-motion components T and R may be described in terms of 6 degrees of freedom. Translation components along the x-, y-, and z-axis are called thrust, sideslip, and lift, respectively. Rotation components along the same axes are called roll, pitch, and yaw. (b) The variables θ_x , θ_y , and θ_z describe the angles between the direction, d_i , upon which the parallax vector, p_i , is observed, and the cardinal axes of the coordinate system. We will need those angles later during the discussion of local scaling factors applied to the observation directions, d_i . In this case, the parallax vector has been observed during a translation, T , along the positive z-axis. Note that the angles θ_i , ($i = x, y, z$), are different from the

angle Θ between the observation directions, d_i , and the self-motion vectors T or R . In the example given here, where the self-motion vector, T , corresponds to the positive z-axis, the angle $\Theta = \theta_z$. As the visual field is spherical, we may represent local image shifts, p_i , as tangent vectors on the surface of a unit sphere. The directions of R , T , and d_i may be described in terms of two angles, the horizontal azimuth, α , and the vertical elevation, β . The azimuth ranges from $-180^\circ \leq \alpha \leq 180^\circ$, with $\alpha = 0^\circ$ corresponding to the positive x-axis in Cartesian coordinates and the elevation ranging from $0^\circ \leq \beta \leq 180^\circ$, where $\beta = 0^\circ$ corresponds to a direction along the positive z-axis; and $\beta = 90^\circ$ describes the equator of the visual field

another, we should first consider the translation- and rotation-dependent contributions on the right-hand side of Eq. 1 separately. Let us assume the optical system undergoes a pure unit translation along the positive x-axis, i.e., $T = [1 \ 0 \ 0]^T$. The resulting image shift is observed in direction $d_i = [0 \ 1 \ 0]^T$, which corresponds to the positive y-axis and thus a lateral viewing direction at the equator of the visual field (Fig. 2a). In this case, T and d_i are orthogonal to one another and the dot product ($T \cdot d_i$) becomes zero. The result is a parallax vector, p_i , that is equal to $-T$ which may be plotted as a tangent vector in a spherical representation of the visual field with its basis originating at d_i (Fig. 2a). The translation-dependent term in Eq. 1 states that p_i is scaled by the distance, D_i , between the center of the optical system and the point in the visual field along direction d_i . We can easily relate this distance dependence to our everyday experience. When sitting on a train or in a car moving along a straight line, close visual objects rush past very quickly, while trees or hills in the distance seem to hardly move at all.

In contrast to the translation-induced contribution to the parallax vector, the rotation-induced contribution does not depend on distance, as is clear from the second term on the right-hand side of Eq. 1. During a pure counterclockwise rotation of the optical system around the positive x-axis, $R = [1 \ 0 \ 0]^T$, we chose the same observation direction as before, $d_i = [0 \ 1 \ 0]^T$, and calculate the cross product, $-(R \times d_i)$, to obtain the rotation-induced local parallax vector, p_i (Fig. 2b). Like in a case of translation-induced relative motion, the resulting p_i plotted as a tangent vector on the sphere points in the direction opposite to the change of d_i over time (Fig. 2b).

In the next step, we may apply Eq. 1 to compute optic flow fields composed of parallax vectors measured at N different directions, d_i , in the visual field. Again we consider the global properties of translation- and rotation-induced optic flow fields separately. This time we compute a pure lift translation, $T = [0 \ 0 \ 1]^T$, and again a pure roll rotation, $R = [1 \ 0 \ 0]^T$. For this purpose, we set in Eq. 1 the

Optic Flow Processing, Fig. 2 Local motion parallax vectors due to translation and rotation. (a) Translation-induced local parallax vector, p_i , observed at direction, d_i , given a thrust translation, T , along the positive x-axis. The distance to objects in the visual environment, D_i , was set to

unity. (b) Rotation-induced local parallax vector, p_i , observed at direction, d_i , given a counterclockwise roll rotation, R , around the positive x-axis. For further explanation, see text

rotation and translation vectors to zero, respectively. To keep matters simple, we assume a uniform distance distribution, i.e., $D_i = 1$, for all directions, d_i , when calculating the translation-induced component of the individual parallax vectors.

Figure 3a, b shows the global structure of such translational and rotational optic flow fields – for clarity all individual parallax vectors were multiplied by a scaling factor of 0.1. The flow fields were calculated for a lift translation (a) and roll rotation (b), respectively. In both cases, the directional distribution of the local parallax vectors is determined by the self-motion vectors R and T . The orientation of R and T defines the location of the two singularities within the optic flow fields where the magnitude of the local image shifts, or parallax vectors p_i , becomes zero. The singularities are separated by an angle of 180° . Right in between the two singularities, i.e., 90° off the orientation of R and T , the projection of the relative motion becomes maximum, which is easily verified by revisiting the rotation- and translation-dependent terms in Eq. 1. At any other location, the magnitude of the parallax vectors follows the function $|p_i| = \sin(\Theta)$, where Θ is the angle between the self-motion component and the observation direction d_i . In translation-induced optic flow fields, the two singularities are often referred to as focus of expansion (FOE), located in the direction of translation T ,

and the focus of contraction (FOC) in the opposite direction $-T$. Singularities within a rotation-induced flow field coincide with the orientation of the axis of rotation (AOR), defined by R and $-R$.

A fundamental difference in the global structure of translation- and rotation-induced optic flow concerns the respective directional distribution of the parallax vectors. While all image shifts p_i within a translation flow field are aligned along great circles connecting the FOE with the FOC, image shifts in a rotation flow field are oriented along parallel circles centered on the AOR (Fig. 3a, b). Another general feature of translational and rotational parallax vectors is that at any given direction d_i , they are orthogonally oriented to one another when the self-motion axes of translation and rotation are co-aligned. This means that they can be most easily distinguished, which is a helpful feature when extracting translation- and rotation-induced self-motion components.

For various reasons, it has proven useful to transform the spherical representation of optic flow into a 2-dimensional cylindrical projection. Such dimensionality reduction naturally comes with an increasing transformation error toward the pole regions of the sphere where the area is overrepresented by a factor of $1/\sin(\beta)$, with β being the elevation (cf. legend Fig. 2). A cylindrical projection, however, allows us to

Optic Flow Processing, Fig. 3 Global structure of optic flow fields. (a) Optic flow field generated during lift along the positive z-axis. The distance to objects in the visual environment, D_o , was set to unity. FOE and FOC give the focus of expansion and contraction, respectively, which are defined by the translation vector, T , and indicate the two singularities in the flow field. (b) Optic flow field generated during roll rotation, R , around the positive x-axis. AOR stands for axis of rotation which defines the two singularities in the flow field. To visualize the entire global flow field, it may be transformed into the two-dimensional plane using a cylindrical projection. For better

intuition when presenting the flow field, the elevation, β , has been redefined to range from $+90^\circ \geq 0 > -90^\circ$. This results in the direction $\alpha = \beta = 0^\circ$ coinciding with the positive x-axis, i.e., the location in the equator of the visual field in front of the observer (f). Letters d , v , and c stand for dorsal, ventral, and caudal, respectively. Note that in the equatorial region in the right lateral hemisphere (gray area), the parallax vectors point downward in both flow fields; they are ambiguous with respect to the self-motion component that caused them. For further explanation, see text (Modified from Krapp and Hengstenberg 1996)

directly visualize the entire spherical optic flow field in a single figure as a function of azimuth, α , and elevation, β (Fig. 3a, b, right panels).

Estimating Self-Motion Parameters from Noisy Optic Flow Fields

So far we considered the properties of optic flow assuming that all parameters were perfectly well known which enabled us to compute translation- and rotation-induced flow fields. Optical systems – or biological visual systems – generally have to solve the inverse problem. To be useful for guidance and control of technical systems or, equivalently, the control of posture and gaze in animals, the task is a continuous estimation of R and T

which may be used to generate feedback signals driving the appropriate motor plants. I should emphasize that both technical and biological systems have also access to inertial measurements of state changes using accelerometers and gyroscopes or equivalent mechanoreceptive systems. But inertial sensor systems – although being able to initiate immediate stabilizing action – do not necessarily provide information as to whether or not compensatory motor activity has yielded the desired effect. Another problem concerns the dynamic range of the sensors. Some inertial measurement sensors and many mechanoreceptor systems are not particularly sensitive in the low end of their dynamic range resulting in a low gain for sensing slow drifts or angular rotations. Vision, on the other hand, covers the low-end dynamic range

but is notoriously slow due to long delay times and heavy computational overheads when processing local image shifts. Biological visual systems also have limited bandwidth for the processing of image shifts due to high linear and angular velocities. We will return to the topic of dynamic range fractioning further below.

Why exploit optic flow to estimate self-motion? For instance, one of the components in human gaze control is driven by the vestibuloocular reflex (VOR) where the oculomotor pathway receives inputs from the fast vestibular system that measures angular accelerations of the head (e.g., Angelaki and Cullen 2008). Ideally, small head rotations should be quantitatively compensated for by motor action of the eye muscles counterrotating the eye balls in their orbits. But the only way of knowing whether the counterrotation fully compensated for the head or body movement is to measure the remaining relative motion between the eyes and the visual surroundings. Adjusting the motor commands sent to the eye muscles requires an estimate of the rotational optic flow component analyzed by the motion vision system. Another vision-dependent mechanism enabling the control of posture and gaze is the oculomotor reflex. To support an equilibrium posture and a stable gaze also requires an estimate of self-motion parameters $\mathbf{R}$ and $\mathbf{T}$. In general, whenever animals – including humans – are endowed with vision, they will have developed the analysis of optic flow as a mechanism that complements mechanoreception for the control of their motor actions.

In the following, we will discuss the theoretical limits of estimating $\mathbf{R}$ and $\mathbf{T}$ based on noisy optic flow fields. Noise, in this context, may be introduced by internal or external factors, for instance, as a result of imperfections in measurements of local parallax vectors or uncertainties in the distance distribution within the cluttered visual surroundings (see below). As a starting point, it will be useful to revisit the work by Koenderink and van Doorn (1987) who proposed an iterative least square solution for the recovery of $\mathbf{R}$ and $\mathbf{T}$, also known as the KvD algorithm. As Eq. 1 states, we are dealing with an expression that contains one known quantity on the left-hand side – at least under the assumption

that the optical system is able to measure the parallax vectors, $\mathbf{p}_i$. On the right-hand side, the only parameter known is the distribution of directions, $\mathbf{d}_i$, at which the parallax vectors are observed. The unknown parameters on the right-hand side of Eq. 1 are the distances to objects in the visual field, D_i , as well as $\mathbf{T}$ and $\mathbf{R}$. This clearly is an ill-posed problem due to the fact that the contribution to $\mathbf{p}_i$ induced by $\mathbf{T}$ is under-defined. The same $\mathbf{p}_i$ may result from a slow translation at close distance to visual objects or from a fast translation in an environment where the objects are at large distances. Although the contribution to $\mathbf{p}_i$ based on $\mathbf{R}$ is sufficiently well defined, $\mathbf{R}$ and $\mathbf{T}$ cannot be estimated based on a single parallax vector induced during a combination of translation and rotation.

Koenderink and van Doorn (1987) tackled this problem by introducing a local scaling factor μ_i , or “reduced nearness,” defined as $\mu_i = T/D_i$, where T denotes the speed of the translation vector $\mathbf{T}$ along the direction of the unit vector $\mathbf{t}$ according to the relationship $\mathbf{T} = \mathbf{t}T$. By introducing reduced nearness, the KvD turns an ill-posed problem into a tractable one. It allows for the retrieval of the direction of translation vector, $\mathbf{t}$, rotation vector, $\mathbf{R}$, and the local reduced nearness, μ_i , given the parallax vectors, $\mathbf{p}_i$, are measured at $N \geq 5$ different directions, $\mathbf{d}_i$. The introduction of reduced nearness modifies Eq. 1 to.

$$\mathbf{p}_i = -\mu_i(\mathbf{t} - (\mathbf{t} \cdot \mathbf{d}_i)\mathbf{d}_i) - (\mathbf{R} \times \mathbf{d}_i) \quad (2)$$

The KvD is based on minimizing the squared error, E , between a set of measured parallax vectors, $\mathbf{p}_i$, and a set of parallax vectors, $\mathbf{p}'_i$, calculated from fitted parameters $\mathbf{t}'$, $\mathbf{R}'$, and μ'_i , under the constraint that $|\mathbf{t}'| = 1$. The error E is formalized by.

$$E = 1/N \sum (\|\mathbf{p}_i - \mathbf{p}'_i\|)^2 + \lambda((\mathbf{t}' \cdot \mathbf{t}') - 1), \quad (3)$$

where λ is the Lagrange multiplier ensuring the constraint $|\mathbf{t}'| = 1$ is met. After working out the partial derivatives $\partial/\partial \mathbf{R}'$, $\partial/\partial \mathbf{t}'$, and $\partial/\partial \mu'_i$ for the right-hand side of Eq. 3, three equations are obtained which can be used in an iterative procedure to estimate $\mathbf{t}'$, $\mathbf{R}'$, and μ'_i :

$$\mathbf{t}' = -v \left\{ [\mathbf{I} - \langle \mu'_i \mathbf{d}_i \otimes \mu'_i \mathbf{d}_i \rangle]^{-1} [\langle \mu'_i \mathbf{p}_i \rangle + (\mathbf{R}' \times \langle \mu'_i \mathbf{d}_i \rangle)] \right\}, \quad (4a)$$

$$\mathbf{R}' = [\mathbf{I} - \langle \mathbf{d}_i \otimes \mathbf{d}_i \rangle]^{-1} [\langle \mathbf{p}_i \times \mathbf{d}_i \rangle + (\mathbf{t}' \times \langle \mu'_i \mathbf{d}_i \rangle)], \quad (4b)$$

$$\mu'_i = -\mathbf{t}' \cdot (\mathbf{p}_i - (\mathbf{d}_i \times \mathbf{R}')) / (1 - (\mathbf{t}' \cdot \mathbf{d}_i)^2), \quad (4c)$$

where $\mathbf{I}$ is the identity matrix, v is a factor forcing $|\mathbf{t}'| = 1$, $\otimes$ symbolizes the dyadic (tensor) product, and arguments in pointed brackets, $\langle \dots \rangle$, are averages over all N observation directions. It is worth discussing the terms on the right-hand side of the iteration equations for the estimate of $\mathbf{t}'$ and $\mathbf{R}'$ more closely.

Apparent translation and rotation: It may come as a surprise to find the cross product between the estimated rotation and the average across all observation directions multiplied by the reduced nearness, $(\mathbf{R}' \times \langle \mu'_i \mathbf{d}_i \rangle)$, in the iteration equation for the estimate $\mathbf{t}'$. Similarly, in the equation for the rotation estimate, $\mathbf{R}'$, the term $(\mathbf{t}' \times \langle \mu'_i \mathbf{d}_i \rangle)$ is included. These terms in Eq. 4a and 4b describe the so-called “apparent translation” and “apparent rotation” terms, due to the rotational and translational components of self-motion, respectively (Koenderink and van Doorn 1987). They are the inevitable consequence of the fact that a parallax vector observed in direction $\mathbf{d}_i$ could have been the result of a translation *or* a rotation. This is easily illustrated by comparing the same region of two optic flow fields where one was caused by lift translation and the other one by clockwise roll rotation (Fig. 4). The parallax vectors in this region of the equatorial visual field are quite similar and, for the position $\alpha = 90^\circ$, point in exactly in the same direction. The apparent terms, however, do also suggest a practical solution to this problem. The estimates $\mathbf{t}'$ and $\mathbf{R}'$ are both applied to the average $\langle \mu'_i \mathbf{d}_i \rangle$. If the

observation directions are appropriately chosen so that their average is equal to zero, then the cross product with the estimated translation and rotation, and thus the “apparent” terms, also equals zero. The best way to achieve this is a pair-wise observation of parallax vectors in opposite directions. The reason being that parallax vectors in a translation flow field observed at opposite locations in the visual field assume the same direction, but those observed at equivalent locations in a rotation flow field point in opposite directions (cf. Figure 3), which allows us to distinguish between the two cases. The best strategy would certainly be to observe parallax vectors at many paired locations over as large a solid angle as possible – ideally 4π – which would enable the analysis of optic flow generated in both visual hemispheres. We will later show examples of optic flow processing in insects which reflect an approximation of exactly that strategy.

The matrices of observation directions: The results of the averaged dyadic products including nearness estimates $\langle \mu'_i \mathbf{d}_i \otimes \mu'_i \mathbf{d}_i \rangle$ in Eq. 4a and $\langle \mathbf{d}_i \otimes \mathbf{d}_i \rangle$ in Eq. 4b are 3×3 matrices, subtracted from the unit matrix $\mathbf{I}$. These matrices are independent of either $\mathbf{t}'$ or $\mathbf{R}'$ and simply indicate the overall distribution of the chosen directions, $\mathbf{d}_i$, at which parallax vectors $\mathbf{p}_i$ are observed. The same reasoning put forward in the last paragraph as a way to reduce the apparent terms may be applied here, which introduces a very useful simplification of iteration Eqs. 4a and 4b. Assuming a sufficiently high number of pair-wise observation directions reasonably covering the visual field will significantly reduce the off-diagonal elements of the matrices, or even make them disappear (Dahmen et al. 2001). We can then rewrite Eqs. 4a and 4b which may be used as the initial estimates, $\mathbf{t}_0'$ and $\mathbf{R}_0'$:

$$\mathbf{t}_0' \cong - \frac{\langle \mu'_i \mathbf{p}_{x,i} \rangle / \langle \mu_i'^2 \sin^2(\theta_{x,i}) \rangle}{\langle \mu'_i \mathbf{p}_{y,i} \rangle / \langle \mu_i'^2 \sin^2(\theta_{y,i}) \rangle} \quad (5a)$$

Optic Flow Processing, Fig. 4 Processing and integration of directional motion information. (a) The sign and amplitude of the output signal produced by an elementary movement detector (EMD) depends on the direction of motion. Motion in the detector's preferred direction (PD) and anti-preferred direction (anti-PD) results in positive and negative outputs, respectively. M stands for multiplication and τ is the time constant of a filter modeling the delay stage. For further information, see text modified from Borst and Egelhaaf (1989). (b) In the fly hexagonal eye lattice directional motion is analyzed by sets of EMDs (thick black arrows) along the ommatidial rows. Along the vertical rows mostly next neighbor interactions are implemented. The analysis of the two oblique rows is combined to result in horizontal motion sensitivity (thin arrows). Individual detectors will not be able to distinguish

between motion due to translation or rotation. (c) Red lines indicate the orientation of "vertical" rows in the one quadrant of the right eye plotted over azimuth and elevation. The local preferred directions (LPDs, blue vectors) of vertical cells (VS cells) follow roughly the orientation changes of the vertical rows which are most conspicuous in the dorsofrontal part of the eye. Data from Petrowitz et al. (2000). (d) A lobula plate tangential cell (LPTC) integrates the outputs of retinotopically arranged arrays of EMDs. The VS6 cell receives input only from those EMDs, the preferred direction of which is aligned with the direction of local parallax vectors in an optic flow field induced during roll rotation. The VS6 cell receptive field may be considered a matched filter for roll-induced optic flow. For further explanation, see text. (Redrawn from Egelhaaf et al. 2002)

and

$$R_0' \cong \frac{\langle p_{y,i} d_{z,i} - p_{z,i} d_{y,i} \rangle / \langle \sin^2(\theta_{x,i}) \rangle}{\langle p_{z,i} d_{x,i} - p_{x,i} d_{z,i} \rangle / \langle \sin^2(\theta_{y,i}) \rangle} \frac{\langle p_{x,i} d_{y,i} - p_{y,i} d_{x,i} \rangle / \langle \sin^2(\theta_{z,i}) \rangle}{\langle p_{y,i} d_{z,i} - p_{z,i} d_{y,i} \rangle / \langle \sin^2(\theta_{x,i}) \rangle} \quad (5b)$$

where $\theta_{x,i}$, $\theta_{y,i}$, and $\theta_{z,i}$ give the angles between d_i and the cardinal axes of the coordinate system

(cf. Fig. 1b). These initial estimates are obtained in a single calculation step. Given an appropriate distribution of observation directions which minimizes the apparent term in Eq. 4a, the translation estimate, t_0' , is simply obtained from the average across the nearness-scaled parallax vector components, normalized by averages of the products of the squared nearness and observation direction components. Similarly, under the same assumptions regarding the distribution of observation

directions, the rotation estimate, $\mathbf{R}_0'$, in Eq. 4b is based on the averages of the cross products between the parallax vector components and the components of the observation directions, normalized by the averages of the squared components of the observation direction. These initial estimates provide already a fairly decent approximation of the actual self-motion parameters. But in case local parallax vector observations are noisy, the distribution of observation directions has been less favorably chosen, and the distance or nearness distribution is inhomogeneous, the full iteration process using Eqs. 4a, 4b, and 4c clearly improves the results. Choosing a reasonable number of observation directions, say 50, distributed evenly over the 4π visual field enables stable estimates of the three parameters $\mathbf{t}'$, $\mathbf{R}'$, and μ_i' within about 10–20 iterations. Obviously, the exact number of iterations required also depends on the overall noisiness of the observed parallax vectors, $\mathbf{p}_i$.

So far we considered the general case, independent of the nature of the optical system moving relative to a static environment. On the one hand side, it is the beauty of the KvD algorithm that it does not bother about questions concerned with the implementation of mechanisms which enable the measurement of local parallax vectors. The KvD algorithm and later applications of it simply point out the principle limits of retrieving self-motion parameters from optic flow fields. In the next section we will discuss the mechanisms required for detecting the direction of motion in biological visual systems and how specific adaptations in the visuomotor pathway of a simple model system, the common blowfly, shed some light on the strategies underlying neuronal processing of optic flow.

Matched Filter for Optic Flow Processing

When estimating self-motion components from optic flow fields, the visual system does not have the luxury of spending time on an iterative procedure. It also has to solve the problem of the ambiguity of local parallax vectors which may potentially increase the apparent motion terms in

Eqs. 4a and 4b, and it has to establish a neural mechanism that measures the $\mathbf{p}_i$ in the first place. Flying insects, with their compound eyes endowing them with nearly 4π vision, are in a prime position to process optic flow. Depending on the species, they analyze visual motion at around hundreds (fruit flies), thousands (blowflies), or even tens of thousands (dragonflies) of locations spread across the visual field (e.g., Land and Nilsson 2012). This enables them to establish a favorable distribution of observation directions, $\mathbf{d}_i$, which helps to keep the apparent motion terms small. In addition – except for situations where they are subjected to unpredictable disturbances of their flight attitude and trajectory – they may structure their self-motion by alternating phases of translation and rotation, which further reduces the apparent motion terms during the different phases. Such alternating flight patterns have been studied in blowflies and were proposed to play an important role in estimating relative distance from analyzing translational optic flow (cf. ► “Visual Processing in Free Flight,” this volume).

But how is the local parallax vector analyzed? Ideally, what the visual system needs to measure is the direction and magnitude of the $\mathbf{p}_i$. We should start with a brief introduction of elementary movement detectors (EMDs) which were proposed by Hassenstein and Reichardt (1953) based on a behavioral input–output analysis in beetles several decades ago. The phenomenological model derived from the experimental results reflects the necessary and sufficient conditions required to generate a time-averaged output, the sign of which indicates the direction of motion with respect to the measuring axis of the EMD (rev., Reichardt 1961, 1987). An EMD has to (i) sample light intensity changes at two neighboring locations of the eye, (ii) process the resulting signals in an asymmetric way, and (iii) combine the two signals in a nonlinear way, e.g., approximated by a multiplication operation (e.g., Reichardt 1987; Borst and Egelhaaf 1989, 1993). The fully opponent EMD consists of two mirror-symmetrical half-detectors, the outputs of which are subtracted from one another at a common integration stage. As a result, at the integration

Optic Flow Processing, Fig. 5 Receptive field organization of VS cells in the fly motion vision system. The upper panels show a morphological reconstruction based on injections of fluorescent dye during intracellular recordings from the cells. (a, bottom): Local preferred directions (LPDs) and motion sensitivities (LMSs) were determined from visual motion stimulation within small fractions of the receptive field at different positions in terms of azimuth, α , and elevation, β . LPDs and LMS define the orientation and length of each individual vector. The LPD distribution of the VS6 cells is highly similar to the

distribution of the local parallax vectors, p_i , in an optic flow field induced by a counterclockwise roll rotation. There is a conspicuous dorsoventral asymmetry in the LMS distribution which differs from the symmetrical distribution of magnitudes in a roll-induced flow field. (b, bottom): LPD and LMS distribution within the receptive field of the VS8 cell. While the LPDs reflect the preference of this cell for a body rotation in between roll and pitch (cf. singularity at $\alpha = 45^\circ$ and $\beta = 0^\circ$), the LMS distribution shows a similar asymmetry as found in the receptive field of the VS6 cell. (Redrawn from Krapp et al. 1998)

stage, motion in the preferred (PD) and anti-preferred direction (AD) of the detector produces on average a positive and a negative signal. Figure 5b shows a simplified version of an EMD. The model basically performs a spatio-temporal correlation of light intensity changes at adjacent positions in the eye. A mathematical description of the computational properties of EMDs in the invertebrate (e.g., Reichardt 1987) and the vertebrate visual system (e.g., Adelson

and Bergen 1985) suggests that the basic functional structure of correlation-based EMDs is quite ubiquitous (Borst and Euler 2011).

In terms of the potential implementation of the EMDs in the visual system of flies, two stages were identified a long time ago. As confirmed by quantitative behavioral experiments in fruit flies (Buchner 1976) and later electrophysiological studies in blowflies (Riehle and Franceschini 1984), the inputs to the EMDs in the compound

eyes of insects are provided by individual facets, or ommatidia, arranged in the hexagonal eye lattice. Ample electrophysiological evidence obtained in blowflies suggested that the subtraction stage may correspond to the dendrites of wide-field motion-sensitive interneurons in the posterior part of the third visual neuropile, the lobula plate (e.g., Hausen 1984). How and where the core operation of the EMD, i.e., the nonlinear combination of the two input signals, may be implemented remained unclear but is currently under heavy investigation in the fruit fly using neurogenetical approaches (cf. ► “Visual Motion Detection in *Drosophila*,” this volume).

Regarding optic flow processing in insects, the key message is that in any observation direction a set of EMDs with different preferred directions analyze local image motion and thus the system has access to a quantity that is related to the parallax vectors $\mathbf{p}_i$. I will later discuss the issue that the output of an EMD is not linear in the velocity domain, but depends on several parameters describing the spatiotemporal properties of the motion stimulus. The next question is: How may the self-motion parameters $\mathbf{t}$ and $\mathbf{R}$ be recovered in a non-iterative fashion?

We should revisit Eqs. 5a and 5b which provide the initial estimates of the self-motion parameters. An intuitive interpretation would be based on the following example proposed by Dahmen et al. (2001) in a slightly different notation: To retrieve the rotation component $\mathbf{R}_a$ around axis $\mathbf{a}$, we design a directional template, $\mathbf{U}_a^R$, which consists of a set of unit vectors $\mathbf{u}_{a,i}^R$ that are all aligned with flow vectors induced by the rotation around $\mathbf{a}$ observed at directions $\mathbf{d}_i$:

$$\mathbf{U}_a^R = -[\mathbf{a} \times \mathbf{d}_i]/\sin\theta_i, \quad (6)$$

where θ_i gives the angle between $\mathbf{a}$ and $\mathbf{d}_i$. To evaluate the contributions of the local parallax vectors of the current optic flow field to $\mathbf{R}_a$, all $\mathbf{p}_i$ are projected onto the local template vectors $\mathbf{u}_{a,i}^R$:

$$m_i^R = \mathbf{p}_i \cdot \mathbf{u}_{a,i}^R = [\mathbf{p}_i \times \mathbf{d}_i] \cdot \mathbf{a}/\sin\theta_i. \quad (7)$$

Averaging over all contributions m_i^R multiplied by $1/\sin\theta_i$, we make sure we obtain properly scaled contributions of the flow vectors $\mathbf{p}_i$ to the rotational component $\mathbf{R}_a$. The best *one-step* estimate of the alignment between the current rotation and a rotation around the specific axis, $\mathbf{a}$, is obtained by applying weighting factors $w_i^R = \sin^2\theta_i$ to the average of the local projections, which is consistent with the result of Eq. 5b.

Similarly, we may construct a directional template $\mathbf{U}_a^t$ to estimate the component $\mathbf{t}_a$ along unit translation $\mathbf{a}$ where the unit vectors $\mathbf{u}_{a,i}^t$ at observation directions $\mathbf{d}_i$ are parallel to the parallax vectors induced by $\mathbf{a}$:

$$\mathbf{U}_a^t = -[\mathbf{d}_i \times \mathbf{a}] \times \mathbf{d}_i/\sin\theta_i. \quad (8)$$

The projection of the current $\mathbf{p}_i$ onto the local template directions $\mathbf{u}_{a,i}^t$ results in local contributions:

$$m_i^t = \mathbf{p}_i \cdot \mathbf{u}_{a,i}^t = \mathbf{p}_i \cdot \mathbf{a}/\sin\theta_i \quad (9)$$

We again scale, this time by $1/\mu_i \sin\theta_i$, taking into account the relative nearness or inverse distance, and average across all contributions after applying local weightings $w_i^t = \mu_i^{-2} \sin^2\theta_i$ to arrive at Eq. 5aa.

These considerations on best *one-shot* estimates – based on specific directional templates – allow us to make some predictions about the properties of any neural mechanisms underlying the processing of optic flow to recover self-motion information. For one, neurons involved in this functional context should respond to visual motion in a directional-selective way. Secondly, they should have extended receptive fields, ideally comprising both visual hemispheres, to reduce the ambiguity inherent to local parallax vectors (apparent terms). And finally, to be able to act as templates matching the directional distribution of local parallax vectors in a specific optic flow field, their directional preference should depend on the directions in which they analyze local visual motion.

Response Properties of Lobula Plate Tangential Cells

I mentioned earlier that the common integration stage of the two EMD half-detectors was localized on the dendritic input arborization of large motion-sensitive interneurons in the fly lobula plate. These lobula plate tangential cells (LPTCs) have long been studied in dipteran flies with respect to their morphology and physiological response properties, mostly in blowflies (Hausen 1984, 1993; ► “Visual Processing in Free Flight,” this volume) and more recently in fruit flies (► “Visual Motion Detection in *Drosophila*,” this volume). In each half of their visual system, blowflies employ about 60 individually identified LPTCs (e.g., Hausen 1993) which receive input from retinotopically arranged local motion-sensitive neurons, the function of which was suggested to be equivalent to the elements of the EMD providing half-detector outputs (e.g., Borst and Egelhaaf 1989). According to their morphology, physiology, or function, LPTCs may be divided into three classes: cells tuned to the movement of small moving objects that are involved in figure-ground discrimination (FD cells, e.g., Egelhaaf 1985), intrinsic cells contributing to the neural mechanisms underlying figure-ground discrimination (CH cells, e.g., Hausen 1984), and heterolateral cells propagating motion information to the contralateral lobula plate by means of action potentials (H cells and V cells, e.g., Hausen 1993) and two distinct subpopulations constituting the horizontal system, HS (Hausen 1982), and the vertical system, VS (Hengstenberg 1982). The three HS and ten VS cells in the blowfly encode motion information in a mixed signal mode, a combination of graded membrane potentials and action potentials (Hengstenberg 1977). They are chemically and electrically connected to multimodal descending neurons (Strausfeld and Seyan 1985; Gronenberg and Strausfeld 1990; Gronenberg et al. 1995; Haag et al. 2007) and motor neurons (Strausfeld et al. 1987) which, in turn, provide various motor systems with sensory feedback in the context of stabilization reflexes as well as object detection and collision avoidance (e.g., Taylor and Krapp

2007; Krapp and Wicklein 2008; ► “Visual Processing in Free Flight,” this volume).

There are an excessive number of publications available on the response properties of LPTCs which were used as model systems to study a large variety of fundamental questions in neuroscience ranging from the nature of the neural code and circadian rhythms in information processing to dendritic integration and sensorimotor control. In this context, I will focus on the HS and VS cells and their role in optic flow processing. These cells have extended receptive fields and respond to visual motion in a fully opponent way: They produce graded depolarizing membrane potential shifts and action potentials when the cells are stimulated in their preferred direction and are hyperpolarized upon visual motion in their anti-preferred direction (e.g., Hausen 1984). Because of their physiological properties, these cells were identified as ideal candidates for processing optic flow and estimating the fly’s self-motion parameters.

A detailed electrophysiological analysis of the distribution of local preferred directions at many locations within the receptive fields of tangential cells has, in most cases, shown a high degree of similarity with the distribution of local velocity vectors in specific optic flow fields (Krapp and Hengstenberg 1996). This suggested that the ten VS cells, for instance, are involved in estimating body rotations of the fly around horizontal axes, while the receptive fields of two out of the three HS cells were found to be matched to optic flow fields induced during rotations about slightly different vertical rotation axes (Krapp 2000; Taylor and Krapp 2007). More recent research provides evidence that HS cells are also involved in global distance estimation based on the processing of optic flow during phases of translational self-motion (e.g., Lindemann et al. 2005; ► “Visual Processing in Free Flight,” this volume).

Figure 5 shows the receptive field organization of two VS cells, VS6 and VS8. Here, each individual vector plotted over azimuth and elevation indicates the local preferred direction (LPD) and local motion sensitivity (LMS) to a locally confined directional motion stimulus (Krapp and Hengstenberg 1997). By applying the KvD

algorithm, the specific rotation axes these cells are tuned to could be calculated. The VS6 cell would respond best during a roll rotation of the animal (cf. Figs. 3a and 5a), while the VS8 cell prefers rotation around an axis between the roll and the pitch axis of the animal (Krapp et al. 1998). The results suggested that the receptive fields of the majority of LPTCs studied so far can be interpreted as matched filters for optic flow where each individual LPD may represent a weighted local unit vector, $\mathbf{u}_{a,i}^R$, of a directional template, $\mathbf{U}_a^R$, as described in the previous section. By selectively integrating the outputs of EMDs, the preferred direction of which is aligned with the directions of local parallax vectors in a specific optic flow field, the output of the LPTC signals the very self-motion component that has caused it (Fig. 4d).

Several studies on the receptive field organization of LPTCs suggested that the LPDs are virtually set in stone (Krapp 2014). They are innate and do not require any early visual experience for the development of their specific distribution (Karmeier et al. 2001) and are related to the orientation of the ommatidial rows within the hexagonal eye lattice (Fig. 4) along which directional motion is analyzed (Buchner 1984). The stimulus-invariant conservation of the LPDs is in fact a necessary condition that enables LPTCs to estimate self-motion parameters from the optic flow fields the fly experiences (Krapp et al. 2012).

A very different situation is found for the LMS distribution within the receptive fields. The first marked difference between the magnitude distribution of parallax vectors in rotational optic flow fields and the LMS distribution found in VS cells is that the former is symmetric with respect to the flow field singularity, while the latter is not (cf. Figs. 3a and 6a). The LMS distribution basically indicates the sensitivity of the cell to directional motion determined as the difference between motion in the preferred and anti-preferred direction – essentially quantifying the height of a directional tuning curve. Many studies have shown in the past that the sensitivity to directional motion in LPTCs depends on a number of stimulus parameters (e.g., Hausen 1984) and the adaptational state of the cell (e.g., Harris

et al. 2000) as well as the animal's locomotor state (e.g., Longden and Krapp 2009; Maimon et al. 2010).

How can we interpret the LMS distribution in LPTCs? Taking an engineering perspective and considering the LPTCs as *optimized matched filters* for optic flow to estimate the translation and rotation components of self-motion may provide an answer to this question.

Optimized Matched Filters for Optic Flow

To appreciate the LMS distribution in LPTCs, we combine aspects of the KvD algorithm with the concept of the one-step estimate outlined in the section before the last. Taking into account Eqs. 6, 7, 8, and 9, we may rewrite Eqs. 4a and 4b to quantify the output of matched filters tuned to a unit self-motion $\mathbf{a}$:

$$t_{a,0} = n \langle \mu_i^2 \sin \theta_i \mathbf{p}_i \cdot \mathbf{u}_{a,i}^t \rangle, \quad (10)$$

$$R_{a,0} = n \langle \mu_i^2 \sin \theta_i \mathbf{p}_i \cdot \mathbf{u}_{a,i}^R \rangle, \quad (11)$$

where n is a suitable normalization factor. As described in the section on *one-step* estimation, $\mathbf{u}_{a,i}^t$ and $\mathbf{u}_{a,i}^R$ are unit vectors aligned in parallel with optic flow vectors induced by translation or rotation along or around $\mathbf{a}$, respectively (Dahmen et al. 2001). This simple model predicts a dependence of the LMSs on $\sin \theta_i$, where θ_i is again the angle between the self-motion axis, $\mathbf{a}$, and the observation directions, $\mathbf{d}_i$, here represented by the unit vectors $\mathbf{u}_{a,i}$. As mentioned in the last section, such $\sin \theta_i$ -dependence was not found in the receptive field organization of the VS cells where the LMS distributions show a pronounced dorsoventral asymmetry.

A generalized model of an optimized matched filter proposed by Franz and Krapp (2000) implements the basic structure given by Eqs. 10 and 11 but introduces two modifications: (i) It applies weightings to the local contributions replacing the factors $\sin \theta_i$, and (ii) it assumes a velocity function, f , modeled after the temporal frequency

Optic Flow Processing, Fig. 6 Optimized matched filters for optic flow processing. Panels (a) and (b) show experimental data and model predictions regarding the weighting of local motion information. In LPTCs matched to rotational optic flow fields (VS6), the sensitivity to ventral motion is reduced. In cells matched to translational optic flow (Hx), the sensitivity distribution is inverted with

higher sensitivity in the ventral visual field. The model predicts a weighting of local parallax vector measurements which is in agreement with the experimental data. Optimal weights may reflect assumptions the visual system makes regarding the mean relative distance distribution within the visual environment. For further explanation, see text. (Data redrawn from Franz and Krapp 2000)

dependence of the EMD outputs (cf. previous section) to result in a filter response:

$$r = n \langle w_i f(\mathbf{p}_i \cdot \mathbf{u}_{a,i}) \rangle. \quad (12)$$

In a model described by Eqs. 10 and 11, the dot product between the parallax vectors, $\mathbf{p}_i$, and the template vectors, $\mathbf{u}_{a,i}$, implies a linear relationship between response and velocity of the form $f(x) = x$. This approximation is only valid within a range where the response of LPTCs is a monotonic function of velocity. Beyond that velocity range, the responses remain at a peak level before dropping off as the stimulus velocity is further increased. One way of modeling the nonlinear velocity characteristic of the EMDs is to introduce

a threshold value, P , below which the output is set to zero and above which the output is normalized to unity. Such a *plateau model* provides equalized responses in those cases where $|\mathbf{p}_i \cdot \mathbf{u}_{a,i}| > P$ and is formalized by.

$$r = n \langle w_i (\mathbf{p}_i \cdot \mathbf{u}_{a,i}) / |\mathbf{p}_i \cdot \mathbf{u}_{a,i}| \rangle. \quad (13)$$

We can now derive an analytical solution for the optimal weight applied in Eq. 13 which can be interpreted as the LMS distribution within the receptive fields of the VS cells. To define an optimality criterion, the following properties of optic flow fields in connection with the environment the filters will be used in may be considered: Translation-induced optic flow contributions

depend on the distance to visual objects in the surroundings. In case we are interested in estimating the rotation parameter, those contributions should be minimized so that the output of the optimized matched filter robustly indicates rotation. Assuming that the rotation of interest always occurs in combination with a broad variety of possible translations in a simplified “world model” approximating the average distance distribution of the environment, we could try to find the sets of weights, w_i , that minimizes the variance of the filter’s output. To describe the translations, a symmetrical 2-dimensional von Mises distribution with a center of mass in the thrust direction may be used. The world model assumes the average distances in the dorsal visual field to be twice as large as the distances in the ventral visual field, with an isotropic distribution of local variances, which essentially looks like a sphere, the bottom half of which is flattened. Finally, an additive uniform noise variance, σ_i , is included locally that takes into account stochastic variations in the output signals of the EMDs (for details, see Franz and Krapp 2000).

Under these assumptions, the optimal weight set for a matched filter indicating rotation is given by.

$$w_i = n \left\langle (\mathbf{p}_i \cdot \mathbf{u}_{a,i})^2 \right\rangle / (\Delta t_i^2 + \Delta \sigma_i^2), \quad (14)$$

where n ensures that the sum of all w_i in the *plateau* model causes a filter output of 1, Δt_i^2 is the local variance induced by the distance variability, and $\Delta \sigma_i^2$ gives the local noise variance. In observation directions where the average distance is small, the relative local distance variability is larger, and due to a larger contribution to the local parallax vector caused by translation, $\mathbf{t}$, along $\mathbf{u}_{a,i}$, the term Δt_i^2 becomes particularly large. As a result, local weights assigned to those directions, which are in the ventral visual field, are small. This corresponds to the LMS distribution found in the VS cells (Fig. 6a). A χ^2 test to assess the goodness of fit between the model-derived weights and the measured LMSs based on χ^2 -values did not indicate a significant difference between the two distributions.

Depending on the velocity function, f , implemented in the model, different optimal weights were predicted with respect to their dependence on the angle Θ between the filter’s preferred axis, $\mathbf{a}$, and the observation directions. Although both models produced a dorsoventral asymmetry for the weights, in case of the linear model, the weights showed a $\sin \Theta$ -dependence, which is in agreement with Eq. 13 but significantly different from the experimental data. The plateau model, assuming unit contributions from EMDs when the threshold value P was exceeded, resulted in a $\sin^2 \Theta$ -dependence which, as mentioned above, was consistent with the LMS distributions found in the receptive fields of the VS cells (Franz and Krapp 2000).

The same approach applied to predict the optimal weights of a matched filter that indicates a specific horizontal translation produced a distribution similar to that of LMSs found within the receptive field of an LPTC that resembles a translational optic flow field. In this case, the dorsoventral asymmetry was inverted. Locations in the ventral part of the receptive field were assigned higher weights than those in the dorsal part – a result that, again, was in agreement with the experimental findings (Fig. 6).

Taking into account the modeling results, the dorsoventral asymmetry of the LMS distribution in LPTCs can be easily interpreted from the functional point of view. An optimal matched filter that indicates the presence of a specific rotation component should do so no matter what translation the animal is engaging on at the same time. As the fly is likely to maneuver closer to the ground than to the sky, it will introduce substantial translation-induced contributions to the local parallax vectors especially in the ventral visual field. Reducing the weights in the ventral visual field will reduce those contributions. The higher weight given to measurements of parallax vectors in dorsal visual field where the distances are larger makes perfect sense as translation-induced optic flow is scaled down by its distance dependence. Applying a similar rationale, the inverted sensitivity or weight distribution in matched filters estimating translation components may also be readily explained. In this case, more reliable signals are expected in the

ventral visual field, while the dorsal visual field would feature stronger contributions to the filter output by unwanted rotation-induced parallax vectors. An interesting observation regarding the LMS distribution of all ten VS cells is that their dorsoventral asymmetry shows the same dependence on elevation. It is tempting to assume that this asymmetry in the LMS distribution reflects an internal model of the average distances in the world the fly has developed over the time course of evolution.

Conclusions

The beauty of the concept of optic flow is that it allows us to clearly point out what can and what cannot be retrieved from visual relative motion in terms of self-motion parameters. Inspired by Gibson (1950) and thoroughly developed formally by theoretician and computer vision scientists (e.g., Koenderink and van Doorn 1987; Barron et al. 1994), it has certainly benefited research in visual neuroscience over the last few decades, in particular the work on arthropods. Although vertebrates such as primates and birds have long been studied regarding the neural mechanisms underlying optic flow processing (e.g., Lappe 2000), in these animals, a straightforward application of the mathematical framework to the local receptive field properties of individual cells has hardly been achieved. One of the reasons is that cells in visual areas concerned with higher-order motion vision in monkeys, such as MST and MSTd, have highly nonlinear integration properties. Local motion stimuli, which were successfully used in flies, are mostly ineffective to induce measurable responses in otherwise directional-selective cells. Only if comparatively large areas are presented with motion patterns ($\varnothing > 30^\circ$) the cells respond to rotational or translational flow field approximations but may as well not show a high degree of specificity (e.g., Tanaka et al. 1989, 1993; Duffy and Wurtz 1991a, b). A characterization regarding flow field specificity in the pigeon basal optic root has been quite successful (e.g., Wylie and Frost 1999) – in particular the evidence of a common reference frame for optic flow processing neurons and the measuring axes of the semicircular canals

in the vestibular system (Wylie et al. 1998). But again, detailed mappings of local directional preferences, as achieved in the fly, have not yet been obtained.

Despite their small size which has been a major limitation for electrophysiological studies, one of the great advantages of flies is that they are complex enough to address fundamental questions in neuroscience and yet simple enough to obtain conclusive answers. Their limited behavioral repertoire, which in many cases allows for a quantitative input–output characterization, provides a well-defined context for what the nervous system is required to achieve. In particular with respect to visuomotor control, flies are among the most successful model systems used. Their motion vision pathway supporting flight and gaze control has been – and still is – exceptionally well studied using a combination of neuroanatomical, electrophysiological, and computational approaches which may be directly linked to specific behavioral tasks. By applying neurogenetics in fruit flies, major progress has been made over recent years to identify the neural correlates of the EMD (► “Visual Motion Detection in *Drosophila*,” this volume), the holy grail not only for invertebrate researchers but also regarding the question of how neurons multiply.

Despite the considerable level of detail at which motion vision in flies has been studied and our recent advances in understanding the neural mechanisms underlying optic flow processing, there are still a number of unsolved issues to consider. In the context of the VS cells, one of the questions is: How is the complex receptive field organization in these neurons achieved? Comparatively, recent research suggested that the VS cells are coupled among each other, either directly by means of electrical synapses or through another interneuron (Haag and Borst 2004). As a consequence, their receptive fields based on retinotopic inputs are smaller along the azimuth if determined in the dendrite than they are when measured in the axon (Elyada et al. 2009). The coupling between the VS cells nicely explains the enormous receptive field extent, which is far bigger than it would be predicted solely based on synaptic input to their dendritic arborization. A question that still needs answering is: How do

the dendritic branches and the axons of the local input elements find each other in the correct directional-selective input layers (Buchner and Buchner 1984) of the lobula plate to establish a specific optic flow template?

Another proximate question concerns the non-linear properties of the EMDs in the velocity domain (Reichardt 1987), the fact that motion and contrast adaptation changes the cells' input–output characteristic (Maddess and Laughlin 1985; Harris et al. 2000) and that local inputs are not linearly integrated on their dendrites (Borst et al. 1995). How useful are the LPTC for behavioral control, if they do not provide a feedback signal that represents absolute velocity?

Before attempting an answer, there is an ultimate question that should be addressed, which was long puzzling people working in the area. Why are there so many LPTCs? The number of VS and HS cells per brain hemisphere is already 13. The two cellular systems alone comprise 26 cells – and there are many more that could function as matched filters for optic flow. From the technical point of view, six cells would be enough to retrieve all possible self-motion components. A potential answer may be related to another heavily researched area in neuroscience concerned with sensorimotor transformations (e.g., Krapp 2010). Sensory signals are normally obtained in local coordinate systems, which – in this case – would be defined by the orientation of the ommatidial rows in the eye lattice (cf. Fig. 4b, c). But what needs to be controlled are motor systems, the pulling planes of which may be described in entirely different coordinates. The mechanisms underlying the transformation from sensory signals into appropriate motor commands could be quite complicated, and a small number of degrees of freedom regarding the motor system may already allow for a vast number of possible solutions, if the problem is not constrained.

The LPTCs seem to perform exactly this task. They integrate local motion information on their dendrites, but their output reflects exactly what is needed to control the behavior: information about specific self-motion components or – more technically – about state changes. Each of them has a preferred self-motion axis, and together the LPTCs set up a high-dimensional coordinate

system, where the number of dimensions is equal to the number of different matched filter axes they cover. The distribution of those axes seems not to be random. After studying the arrangement, it was recently hypothesized that the preferred rotation axes of the VS cells are ideally suited to sense one of the natural modes of motion that flying systems encounter, a “Dutch roll” (Taylor and Krapp 2007). The basic idea is that the sensory coordinate system set up by the LPTCs corresponds to the motor coordinate systems it controls – a design that would considerably simplify a sensorimotor transformation required for flight stabilization (Krapp et al. 2012). For this to work efficiently, one crucial condition has to be fulfilled: The visual system needs to stay aligned with the inertial vector, which means the head has to be stabilized in the horizontal plane.

Evidence in support of this “mode-sensing hypothesis” comes from studies of motor neurons supplying the fly neck muscles which control the animal's gaze (Huston and Krapp 2008). Neck motor neurons receive input from LPTCs such as the HS and VS cells, either directly or via descending neurons (Gronenberg and Strausfeld 1990; Gronenberg et al. 1995). Neck motor neurons have large visual receptive fields and respond to visual motion in almost the same way as LPTCs, but some of them require mechanosensory input simultaneously to generate action potentials, which is a necessary condition for muscle contraction (Huston and Krapp 2009). Figure 7a shows parts of a neck motor neuron receptive field that responds to horizontal motion induced during yaw rotation. Its visual receptive field looks almost identical to the receptive field of a so-called HSE cell. The only difference is that it receives stronger input from the contralateral eye. This large binocular receptive field helps to reduce apparent terms due to translation (cf. Eq. 4b) which makes perfect sense for a neuron that controls head rotations. Using the KvD algorithm on the receptive field organization of each of the neck motor neurons studied, their preferred rotation axes were computed. The resulting distribution of axes is compared in Fig. 7b with the distribution of the preferred rotation axes of all 26 HS and VS cells and shows a high degree of overlap (Huston and Krapp 2008). Almost all neck

Optic Flow Processing, Fig. 7 Visual receptive field of a fly neck motor neuron and the preferred rotation axis distributions of neck motor neurons and LPTCs. (a) The neck motor neuron receptive field is matched to an optic flow field generated by a rotation around a slightly tilted vertical body axis. (b) Preferred axes of neck motor

neurons (red arrows) and LPTCs (blue arrows) show a high degree of overlap, suggesting that the sensory coordinate system (LPTC) and the coordinate system controlling the fly's gaze are co-aligned. For further explanation, see text. (Redrawn from Huston and Krapp 2008)

muscles in flies are innervated only by a single motor neuron. It is likely, therefore, that the pulling planes of the muscles are predicted by the preferred rotation axes of the neck motor neurons, which still needs to be tested experimentally. The results so far are compatible with the idea that the high number of LPTCs may be interpreted along the lines of the mode-sensing hypothesis (Krapp et al. 2012): There should be roughly as many matched filters for specific optic flow fields as there are axes in the motor systems that need to be controlled.

To get back to an earlier question regarding the suitability of LPTC signals for motor control, there is another essential aspect that should be considered. Motion vision alone would not be sufficient to support the high maneuverability and gust tolerance of flies. The limited bandwidth and long processing delays of the visual system are complemented by fast and low latency mechanosensory systems, such as the halteres in dipteran flies signaling angular rotation rates (Hengstenberg 1993) or the antennae measuring air flow changes (Taylor and Krapp 2007). One of the current and future challenges will be to understand how optic flow-based and mechanosensory signals are integrated to control flight and gaze as efficiently as dipteran flies

do. A proof of concept study where matched filters for optic flow were implemented in a linear control engineering framework did indeed enable autonomous flight of a quadcopter (Hyslop et al. 2010). But only if we understand multisensory gaze and flight stabilization well enough to extract the underlying biological control design, we may eventually reach a performance level in artificial micro air vehicles their natural counterparts achieve.

²Coordinated Science Laboratory and Department of Electrical and Computer Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Definition

Emerging results in the information theory of *reliable computation* may yield theoretical predictions on optimal energy allocation to noisy neurons in sensory processing and experimental tests of optimality hypotheses. Predictions come from optimizing structure and energy allocation for given reliable computations with noisy neurons.

Detailed Description

Theoretical neuroscience often relies on optimality principles derived from information theory as an approach to develop hypotheses for experimentally measurable physical properties of the brain, cf. (Varshney et al. 2016) and references therein. Such information-theoretic principles, however, nearly always focus on the brain as an information transmission and storage system, rather than as a *computation* system. On the other hand, a traditional approach in

computational neuroscience is to investigate the properties of specific biologically plausible circuits and architectures. Information-theoretic principles for computation can, however, be used to make predictions on optimal energy allocation for noisy neurons to achieve reliable computation. The basic idea is to understand the fundamental trade-offs among energy, network structure, and computational reliability (Chatterjee and Varshney 2017).

To outline the information theory yielding biological predictions, consider a simple binary L -layer feedforward neural network with n inputs and a single output constructed from neurons with energy-dependent failure rates. Let $\mathcal{N}_\ell$ be the set of neurons in layer ℓ , and let $N_\ell = |\mathcal{N}_\ell|$; the input layer is $\mathcal{N}_1$, and the output layer is $\mathcal{N}_L$ (with only one active neuron). For a neuron $g \in \mathcal{N}_\ell$, let the set of paths to the output neuron be $\mathcal{P}_g$. An L -layer neural network is therefore an L -partite graph, which we denote as $\mathcal{G}_L$.

Inputs to the neural network are ± 1 . The neural network has a fixed connection pattern between neurons in the various layers, e.g., full connectivity or d -regular connectivity between layers, and there are real-valued weights on the edges. For each neuron there is an associated activation function, which has a real-valued input and an output, that is, ± 1 . The input to the activation function is a sum of the outputs of the neurons of the previous layer, weighted by the edge weights.

A neuron g can fail independently of any other neuron with probability ε_g . When a neuron fails, it flips the output from $+1$ to -1 and vice versa. Neuron g consumes energy e_g for its operation, and ε_g depends on e_g . Thus ε_g can be tuned by an appropriate choice of e_g . For a neuron with probability of failure ε_g and energy consumption e_g , let the *energy-failure function* be $\varepsilon_g = \chi(e_g)$, assumed convex and nonincreasing.

The goal in structuring the neural network and allocating energy e_g to each of its neurons is to use the *minimal energy* in computing a given function such that the output is correct for all inputs with probability at least $1 - \delta$, despite the fact individual neurons may have failure rates $\varepsilon_g > \delta$.

A key analysis technique is called *information propagation*. Pippenger (1988) developed the technique of analyzing information flow for δ -reliable computation in noisy logic circuits, which makes use of strong data processing inequalities (Polyanskiy and Wu 2016). Building on this, for δ -reliable computation by a neural network with the same failure probability of each neuron in a layer, the following must be satisfied:

$$\ln \frac{1}{1-h(\delta)} \geq 4 \sum_l \varepsilon^{(\ell)} - \min_{g \in \mathcal{N}_1} \ln |\mathcal{P}_g|, \quad (1)$$

where $\varepsilon^{(\ell)}$ is probability of failure of neurons in layer ℓ . Moreover, the minimum energy consumption for δ -reliable computation is no more than the solution of:

$$\begin{aligned} \min_{\varepsilon^{(\ell)}, 1 \leq \ell \leq L} \sum_{\ell} N_{\ell} \psi(\varepsilon^{(\ell)}) \text{ s.t. } \sum_{\ell} \varepsilon^{(\ell)} \leq \gamma(\delta), \\ \text{and } 0 \leq \varepsilon^{(\ell)} \leq 1 \text{ for all } \ell, \end{aligned} \quad (2)$$

where $\gamma(\delta) = \frac{1}{4} \left(\ln \frac{1}{1-h(\delta)} + \ln \pi^G(L) \right)$ and $\psi = \chi^{-1}$. Using the KKT conditions (Boyd and Vandenberghe 2004) and some structural properties, at the minimum,

$$\begin{aligned} N_1 \psi'(\varepsilon^{(1)}) &= N_2 \psi'(\varepsilon^{(2)}) = \dots \\ &= N_L \psi'(\varepsilon^{(L)}). \end{aligned} \quad (3)$$

For a polynomial energy-failure function $\chi(e_g) = a/(1 + e_g)^{\beta}$, $\beta > 1$, under G and δ for which (3) holds:

$$\varepsilon^{(\ell+1)} = \varepsilon^{(\ell)} (N_{\ell}/N_{\ell+1})^{\beta/(1-\beta)}.$$

This implies a power-law relation between energy consumption per neuron across different layers.

Note the following relations between the model and sensory cortex. First, neurons have energy-failure functions, χ , described by quantal synaptic failure rate ε_g that is nonuniform across different neurons due to heterogeneous energy

allocations for energy efficiency. Second, the volumes and neuron densities of different brain regions in sensory processing can be combined to characterize neuron number N_{ℓ} . Third, neurogeometry yields estimates of neuronal network structural properties, such as neuron degree d and network structure g_L .

Interestingly, neuroenergetic studies show the metabolic glucose rate in different brain regions (essentially e_g) is a power-law function of their degree of connectivity, as above, since the average degree of a neuron is the ratio of the number of neurons in its layer to that in the next layer. A natural approach to test further optimality hypotheses is to see whether the different aspects of neural connectivity, reliability, and energy are all matched to one another as predicted by theory, as in measure-matching (Varshney et al. 2006).

To this end, note that nonuniform allocation rule (3) implies that $N_{\ell} \psi'(\chi(e^{(\ell)})) = c_{G, \delta}$ for each layer ℓ for some constant $c_{G, \delta}$ that depends only on the network and δ . That is, the per-neuron energy ratio between two layers is the ratio of the respective $\psi((\psi')^{-1}(c_{G, \delta}/N_{\ell}))$. For exponential and polynomial χ , $\psi \circ (\psi')^{-1}$ are proportional to $1/N_{\ell}$ and $1/N_{\ell}^{\beta/(\beta-1)}$, respectively. That is, for a polynomial χ , energy allocation should have per-neuron energy be inversely proportional to the number of neurons in the layer to the power $\beta/(\beta-1)$ (exponential is just $\beta = \infty$, so $\beta/(\beta-1) = 1$). As $\beta/(\beta-1)$ is a one-to-one function of β , it is sufficient to measure the power of N_{ℓ} which relates to per-neuron energy.

An immediate interpretation is that with decreasing number of neurons per layer in higher levels of sensory processing, per-neuron energy allocation should increase geometrically toward the output. Failures in initial layers may be masked in subsequent layers, maintaining reliable computation.

Optogenetics

Jessica A. Cardin
Department of Neurobiology and Kavli Institute,
Yale University, New Haven, CT, USA

Definition

Optogenetic tools are a broad class of genetically engineered proteins activated or inactivated by light of an appropriate wavelength. These include activators, such as the Channelrhodopsins, and suppressors, such as the Halorhodopsins and Archaeorhodopsins, along with other variants.

Detailed Description

Microbial Opsins

Many of the optogenetic tools currently in use in mammalian systems are derived from microbial opsins. These generally incorporate light-sensing and ion flux components in the same protein, as in Bacteriorhodopsin (Oesterhelt and Stoeckenius 1971), Channelrhodopsin-1 (ChR1) and Channelrhodopsin-2 (ChR2) (Nagel et al. 2002, 2003), and Halorhodopsin (eNpHR) (Gradinaru et al. 2008; Han and Boyden 2007; Zhang et al. 2007). In response to light stimulation, the Channelrhodopsins undergo conformational changes and allow nonspecific cation flow, resulting in depolarization and increased action potential output (Bamann et al. 2010; Hegemann et al. 2005; Kato et al. 2012; Nagel et al. 2003). In contrast, Halorhodopsin functions as a light-sensitive chloride channel, whose activation leads to hyperpolarization and decreased spike activity (Han and Boyden 2007; Kouyama et al. 2010; Zhang et al. 2007). Archaeorhodopsin functions as a light-sensitive proton pump whose activation likewise leads to hyperpolarization (Chow et al. 2010).

Subsequent engineering of identified microbial opsins has yielded a series of enhancements of opsin expression, light sensitivity, and photocurrent amplitude and kinetics. Modifications to Channelrhodopsin-2 gave rise to improvements in protein trafficking (Boyden et al. 2005; Gradinaru et al. 2007; Nagel et al. 2005), along with faster kinetics (e.g., ChETA) (Gunaydin et al. 2010). Similar enhancement of trafficking reduced opsin toxicity and enhanced insertion into the membrane (e.g., eNpHR3.0; Gradinaru et al. 2008), whereas other modifications increased light sensitivity (e.g., ArchT; Han et al. 2011). An additional series of mutations gave rise to the step function opsins (SFO), which can remain active for long periods (Bamann et al. 2010; Berndt et al. 2009; Yizhar et al. 2011).

Genomic screens have identified new classes of opsins, including one from *Volvox carteri* (VChR1) that was combined in chimeric form with the original ChR1 to produce the C1V1 construct, a Channelrhodopsin with high-amplitude

photocurrents that responds to red-shifted wavelengths (Zhang et al. 2008). Large-scale screens have identified several additional opsins with unique wavelength sensitivities, large amplitude photocurrents, or faster kinetics (Chow et al. 2010; Klapoetke et al. 2014). Most recently, development has focused on wavelength-shifted optogenetic tools that allow discrete optical manipulations of multiple targets in the same preparation or activation of cells deep in the brain via illumination through the skull (e.g., ReaChR, Chromson; Klapoetke et al. 2014; Lin et al. 2013).

Optogenetics in Mammalian Neurons

The first use of a microbial opsin as a tool in mammalian neurons was the introduction of ChR2 into hippocampal neurons *in vitro* (Boyden et al. 2005). This initial finding highlighted the millisecond-level precision of ChR2-mediated control of spike timing. Later innovations incorporated opsin sequences in Cre recombinase-dependent constructs, such as the DIO and FLEX versions (Atasoy et al. 2008; Sohal et al. 2009), and offered a high degree of cell type specificity (Cardin et al. 2009, 2010; Sohal et al. 2009). More recent work has made extensive use of the temporal fidelity and cellular targeting of optogenetics both *in vitro* and *in vivo*. Optogenetic tools have also been used to manipulate neuromodulatory levels (Goard and Dan 2009; Pinto et al. 2013).

Optogenetics provides significant advantages over other direct manipulation techniques, such as electrical stimulation, in dissecting circuit-level interactions. For example, highly specific optical targeting has allowed identification of the impact of sparsely represented local interneurons *in vitro* and *in vivo* (Adesnik et al. 2012; Pi et al. 2013), along with the relative impact of thalamocortical and cortico-cortical projections (Adesnik and Scanziani 2010; Cruikshank et al. 2007). Expression of ChR2 and either eNpHR3.0 or Arch in the same cell type further confers bidirectional control over the activity of targeted populations (Atallah et al. 2012).

A less well-appreciated advantage of optogenetic tools in the intact brain is the ability to extracellularly identify genetically distinct populations of neurons via optical tagging with ChR2, ChETA, or another depolarizing opsin variant (Cardin et al. 2009; Kravitz et al. 2013; Lima et al. 2009; Pi et al. 2013). The responses of ChR2-expressing cells to light pulses occur at short latencies with high temporal fidelity, allowing detection of sparsely represented cells, such as inhibitory interneurons or specific projection cells, whose action potential waveforms are not distinct from those of the surrounding population.

Optical Manipulation in Freely Moving Animals

Optogenetic tools have been successfully used in freely moving or head-fixed behaving animals where stimulation is delivered through an optical fiber to which the animal is tethered, either alone or in combination with electrophysiological recordings (Adamantidis et al. 2007; Adesnik et al. 2012; Aravanis et al. 2007; Gradinaru et al. 2007; Kravitz et al. 2010). Current efforts in technical development include work on wireless optogenetic manipulations in combination with electrophysiological recordings (Wentz et al. 2011).

Optogenetics in Combination with Optical Imaging

Optogenetic tools have been extensively used in combination with a number of imaging techniques *in vitro*. One fruitful approach has been Channelrhodopsin-assisted circuit mapping (CRACM), which allows optical mapping of synaptic inputs to individual neurons (Petreanu et al. 2007). Opsins have also been used in combination with 2-photon imaging *in vitro*, either alone or in conjunction with glutamate uncaging (Chiu et al. 2013; Packer et al. 2012). Although there have been examples of optogenetic tool use in conjunction with 2-photon imaging *in vivo* (Prakash et al.

2012; Wilson et al. 2012), this combined approach has remaining technical limitations.

Opto-fMRI

Optogenetic manipulations are highly compatible with functional MRI scanning. Several initial studies demonstrated that ChR2-mediated activation of excitatory neurons is associated with an increase in local BOLD signals in mice and that such manipulations can be used to confirm long-range connectivity between brain areas (Desai et al. 2011; Kahn et al. 2011, 2013; Lee et al. 2010). Interestingly, activation of inhibitory interneurons may also elicit a local increase in the BOLD signal (Urban et al. 2012), suggesting that cell type-specific optogenetic control may be useful in understanding the origins of the hemodynamic response.

Potential Limitations

Optogenetics has provided a transformative set of tools for neuroscience. Nevertheless, use of these constructs has some well-characterized caveats. The kinetics of individual proteins vary and can significantly impact the onset and offset rates of effective manipulation. In addition, some evidence suggests that ChR2-evoked action potentials may be associated with altered action potential waveforms or neurotransmitter release (Schoenenberger et al. 2011; Zhang and Oertner 2007). Several optogenetic constructs, particularly the Halorhodopsins, have been identified as toxic to neurons over moderate expression times (Gradinaru et al. 2008). Similarly, although Cre-dependent ChR2 mouse lines exist (Madisen et al. 2012), it remains unclear whether constitutive expression of membrane-inserted opsins impairs neuronal health. Finally, the use of optical stimulation at high intensities has been shown to cause optoelectronic artifacts in combination with metal electrodes, leading to large signals that may occlude neural activity (Cardin et al. 2010; Han et al. 2009). However,

each of these caveats may be overcome with appropriate experimental design.

Pain Processing Pathway Models

Steven A. Prescott
Neurosciences and Mental Health, The Hospital for Sick Children, Toronto, ON, Canada
Department of Physiology, University of Toronto, Toronto, ON, Canada

Definition

The main pathways involved in pain processing have been known for some time, but the precise microcircuitry remains surprisingly unclear. This has allowed very different theories of pain processing to persist. Specificity theory holds that pain is qualitatively distinct from other somatosensory percepts and that the underlying circuitry is arranged as labeled lines. Gate control theory holds that all inputs converge and that it is the level of activation in unspecialized neurons that code for pain. The truth lies somewhere in between. The dorsal horn of the spinal cord, which corresponds to the first synaptic relay point, comprises a diverse set of interneurons

Detailed Description

Types of Pain

Pain is usually caused by noxious stimulation – stimulation that has the potential to cause tissue damage. Such pain is referred to as nociceptive. Pain can also arise from damage to or dysfunction of the nervous system. This latter sort of pain, which is referred to as neuropathic, can result from insults to the peripheral or central nervous systems arising from trauma, diseases like diabetes and herpes zoster, or toxicity by chemotherapeutics and antiretrovirals (Baron et al. 2010; Costigan et al. 2009).

Neuropathic pain reflects abnormalities in the processing of somatosensory input. For instance, innocuous mechanical or thermal (warm or cool) stimulation can be improperly perceived as painful, and noxious stimulation can be perceived as more painful than normal. These phenomena are referred to as allodynia and hyperalgesia, respectively. Spontaneous pain (i.e., in the absence of any stimulation) can also occur. The problem is that these symptoms are often poorly controlled by currently available analgesics. For instance, opioids, despite being very effective against nociceptive pain, have a more variable effect on

neuropathic pain and can sometimes paradoxically worsen it.

Pain Theories and Predicted Microcircuitry

Heated debates have been waged over how pain signals are encoded. Those debates have centered primarily around the concept of specificity (Craig 2003; Perl 2007): Are certain neurons specific (i.e., dedicated) for encoding pain or is pain encoded by the activation level in nonspecific neurons? Intensity and gate control theories favor the latter. Specificity theory favors the former. Over the past several decades, experiments have identified neurons in the peripheral and central nervous systems that respond selectively to noxious stimulation, lending support to specificity theory. But numerous other observations are inconsistent with specificity theory, especially regarding the degree to which specificity is strictly maintained in downstream neurons.

The specificity (or tuning) of primary sensory neurons depends on what receptors they express and with what specialized sensory structures (e.g., Pacinian corpuscles, Merkel's disks, etc.) they associate (Gold and Gebhart 2010; Tsunozaki and Bautista 2009). The tuning of downstream central neurons, on the other hand, depends on which primary sensory neurons provide input; in other words, a central neuron will respond selectively to noxious stimulation if that neuron receives input exclusively from specialized nociceptors. An exclusive connectivity pattern such as this is the basis for labeled lines. However, cross-modal interactions – inhibition of pain by touch, inhibition of itch by pain, etc. – argue against labeled lines and suggest, instead, that input from differently tuned primary sensory neurons converge on central neurons (although this does not necessarily imply convergence to the point that central neurons are completely untuned). Notably, such interactions can be revealed by carefully constructed stimuli or by manipulation of the nervous system and also become apparent under certain pathological conditions (see below).

Cross-modal interactions are important if one considers that stimuli typically activate more than one type of primary sensory neuron. This is especially true for complex stimuli with multiple features, but even a simple stimulus involving deflection of a single hair, for example, will co-activate multiple types of sensory neurons given that multiple types of sensory neurons innervate each hair follicle (Abraira and Ginty 2013). It is important to note that tuning means that a neuron responds preferentially to a certain feature of a stimulus; it does not mean the converse, namely, that a stimulus activates only one type of sensory neuron. Therefore, stimuli *co-activate* differently tuned sensory neurons. If those differently tuned neurons give rise to labeled lines (which by definition should not talk to one another), then whether or not non-nociceptors co-activated along with nociceptors is irrelevant for the signal conveyed through the “pain” line. The fact that this is not what happens (i.e., that cross-modal interactions occur) thus suggests that more complicated microcircuitry exists and can read out the co-activation pattern. This is the basis for what has been referred to as population coding (Ma 2012) or, more specifically, as combinatorial coding (Prescott and Ratté 2012; Prescott et al. 2014).

Cross-Modal Interactions

Before reviewing what is currently known about the pain microcircuits and the pathways they form, we will consider a few examples of how stimulation does not always give rise to the expected percept. Like with illusions in other sensory modalities, somatosensory stimuli can be constructed or sensory processing otherwise manipulated in such a way as to trick the nervous system. Knowing how the system can be tricked can give significant insight into how the system is constructed.

Numerous observations suggest that the neural code for burning pain depends on the relative activation of different types of primary afferents that are differentially tuned to temperature. Burning pain can be evoked by noxious hot or cold

temperatures, but it can also be evoked by innocuous warm or cool temperatures under conditions that cause unmasking. First, one must appreciate that certain neurons are maximally responsive to cool, whereas others are maximally responsive to cold but also respond to cool. Despite modestly activating cold-tuned neurons, cool stimulation does not evoke pain *unless* the co-activation of cool-tuned neurons is blocked. Because the fibers of cool-tuned neurons are myelinated, whereas those of cold-tuned neurons are not, propagation in the former can be selectively blocked by ischemia (e.g., via a blood pressure cuff); with myelinated fibers blocked, cool stimulation is perceived as burning. This suggests that input from *cool* fibers masks the input from *cold* fibers until *cold* fibers are very strongly activated (by cold temperatures). Thus, it is not the absolute activation of *cold* fibers that codes for pain; instead, it is the activation of *cold* fibers relative to *cool* fibers that is important (Yarnitsky and Ochoa 1990). Calculating the ratio or difference of those two inputs necessitates that those two inputs eventually converge on a common postsynaptic target. Furthermore, recognizing this coding scheme has clinical relevance insofar as burning pain could potentially be treated by enhancing the activity of certain “masking” neurons rather than focusing exclusively on reducing the activity of “pain” neurons, or perhaps one could manipulate how the difference calculation is performed centrally.

Thunberg’s thermal grill illusion is also illustrative. In this illusion, spatially patterned innocuous warm and cool stimuli evoke burning pain. This involves the same unmasking phenomenon described above, but with an extra twist wherein cool input is masked by adjacent warm input rather than the cool input being blocked by manipulation of the nerve (Craig and Bushnell 1994).

One should recognize that what is referred to as masking in the pain literature bears a striking resemblance to what is called opponency in the retina. According to trichromacy, different colors are encoded by the relative activation of photoreceptor cells tuned to long, medium, or short wavelengths of light (roughly red, green, and blue), with downstream “opponent” cells that receive convergent input calculating the difference in

activation (Solomon and Lennie 2007). Drawing such analogies will likely help in the investigation of pain microcircuits by identifying which motifs one might expect to find there.

Primary Somatosensory Afferents

Somatosensory information is relayed to the spinal cord via primary sensory neurons. Primary sensory neurons all have their cell body located within a dorsal root ganglion (or the trigeminal ganglion in the case of cranial nerves) and are thus commonly referred to as DRG neurons. These sensory afferents can be classified according to their peripheral targets (skin, muscle, viscera, etc.), response properties (mechanosensitive, thermosensitive, etc.), neurochemical phenotype, and conduction velocity. On a gross level, afferents are very commonly designated as A- β , A- δ , or C fibers based on their axon diameter and myelination: A- β fibers are large and thickly myelinated (and therefore rapidly conducting), whereas C fibers are thin and unmyelinated (and therefore slowly conducting), and A- δ fibers are intermediate. It is commonly assumed that all A- β fiber functions are low-threshold afferents, whereas all A- δ and C fibers are nociceptors, but this is false; for instance, many C fibers respond to innocuous thermal or mechanical stimuli. Moreover, many C fibers are polymodal insofar as they respond to mechanical, thermal, and chemical stimulation or to two of those three stimulus modalities. C fibers are also classified according to whether or not they express certain peptides like substance P. In general, increasing knowledge of which ion channels and receptors are expressed in different cell types has led to increasingly sophisticated classification.

Pain Pathways

Sensory information entering the spinal dorsal horn is relayed by second-order neurons to a variety of supraspinal sites including the thalamus, caudal ventrolateral medulla, nucleus of the solitary tract, parabrachial nucleus, and

periaqueductal gray matter (Craig 2003; Dostrovsky et al. 2006). Pain-related sensory information is routed to multiple different areas of neocortex via different thalamic nuclei. In turn, descending tracts modulate processing within the spinal dorsal horn. Descending modulatory inputs include serotonergic fibers from the nucleus raphe magnus, noradrenergic fibers from the locus coeruleus, and GABAergic fibers from the rostral ventromedial medulla (Millan 2002). Figure 1 summarizes the most important pathways, but it is not exhaustive and nor does it include details like the specific thalamic nuclei through which connections to different parts of the neocortex are formed.

Significant processing occurs within the spinal cord before sensory information is relayed to higher areas. This spinal processing has been the focus of much research but the microcircuitry still remains largely unclear and modeling is scarce. The next section summarizes what is currently known.

Organization of the Spinal Cord Dorsal Horn

The central projections of different types of primary sensory neurons terminate in different layers, or lamina, within the spinal dorsal horn (Fig. 2) (Todd and Koerber 2006). Large myelinated A- β fibers also send collaterals into the dorsal columns, and those fibers ascend ipsilaterally to form synapses in the gracile or cuneate nuclei in the brainstem; it is only after this point that second-order neurons cross the midline (i.e., decussate) and ascend contralaterally to the thalamus. Fibers entering the spinal gray matter also form synapses ipsilaterally, and the vast majority of spinal neuron projection neurons decussate at or around the same spinal level before ascending contralaterally to supraspinal sites. The fact that some fibers ascend ipsilaterally whereas other ascend contralaterally is the basis for Brown-Séquard syndrome, which involves, among other changes, ipsilateral loss

Pain Processing Pathway Models, Fig. 1 Schematic of pain processing pathways

Pain Processing Pathway Models, Fig. 2 Afferent termination patterns in the spinal dorsal horn. The spinal dorsal horn is divided into layers or laminae (indicated along *left*). Different types of afferent fibers terminate

preferentially in different laminae. *HTMR* high-threshold mechanoreceptor, *LTMR* low-threshold mechanoreceptor. (Modified from Todd and Koerber 2006)

of fine touch sensation and contralateral loss of pain and temperature sensation after hemisection of the spinal cord. These sorts of clinical observations provided early evidence supporting labeled lines.

Pain-related sensory information is relayed from the spinal dorsal horn to motor neurons in the ventral horn, thus forming the circuits responsible for withdrawal reflexes. As an aside, most behavioral analysis conducted in preclinical animal studies focuses on withdrawal reflexes although such reflexes are not necessarily a good proxy for the perception of pain (Mogil and Crager 2004). Sensory information is also relayed from the spinal dorsal horn to supraspinal sites (see Fig. 1) via projection neurons whose cell bodies are located in laminae 1 and 5. Laminae 3, 4, and 6 are also the source of ascending fibers, but those fibers are not thought to carry sensory information directly associated with pain.

Interestingly, projection neurons comprise as few as 5% of all neurons in lamina I of rat lumbar segments, and although the same might not be true of all species or all spinal levels, it is safe to say that local interneurons predominate in terms of sheer numbers. This interneuron population is extremely heterogeneous and includes both

inhibitory and excitatory neurons (Todd 2010). Unfortunately, existing classification schemes are not comprehensive or consistently applied, which makes deciphering synaptic connectivity patterns especially difficult. Figure 3 summarizes what is currently known about microcircuits in the superficial dorsal horn (laminae 1 and 2) based on painstaking paired recording experiments. The microcircuitry in deeper lamina is even less well understood.

Despite this circuitry not being so well understood, it is nonetheless quite clear that the processing of sensory information at the spinal level is functionally important. For instance, intrathecal application of drugs to block fast inhibitory synaptic transmission can acutely produce spontaneous pain and mechanical allodynia, presumably mimicking the conditions that develop (more gradually) after nerve injury and result in neuropathic pain. Blockade of inhibition can also dramatically expand receptive fields, thus demonstrating that receptive fields are shaped by inhibition rather than being hardwired. Moreover, blockade of inhibition reveals low-threshold sensory input to neurons that are supposedly nociceptive specific. In short, numerous forms of plasticity and modulation occur at the spinal level (Sandkuhler 2009).

Pain Processing Pathway Models, Fig. 3 Microcircuitry in the superficial dorsal horn. Different morphological and physiological cells types are

shown on the *right*. The afferent input to and connectivity between these cell types is summarized on the circuit diagram. (Modified from Prescott and Ratté 2012)

Pain Pathway Models

Computational modeling has been conducted to help understand the basis for different intrinsic spiking patterns and the effects of synaptic changes such as disinhibition, but very little modeling has been conducted at the network level. There was some early work modeling the gate control theory in the spinal cord (Britton and Skevington 1989) but none since, to the best of my knowledge. Thalamocortical dysrhythmia, which is implicated in neuropathic pain, has been the focus on some recent modeling (Henning Proske et al. 2011). Overall, it is safe to say that the pain system has seen very little network-level modeling. This at least partly reflects the lack of

experimental data that are critical for building certain types of models: What are the cell types? How are they connected? How do those connections change under certain conditions? But by the same token, modeling might go a long way towards helping direct future experiments. For example, modeling could be used to help predict which microcircuit motifs exist within the spinal dorsal horn in order to carry out certain computations that are known, or suspected, to occur (Prescott and Ratté 2012). Modeling could also be used to help predict what computational processes go awry under conditions leading to neuropathic pain. The opportunities are plentiful and understanding of pain processing would greatly benefit from the insights modeling provides.

Parametric Spectral Analysis

Mingzhou Ding¹ and Govindan Rangarajan²

¹The J. Crayton Pruitt Family Department of Biomedical Engineering, University of Florida, Gainesville, FL, USA

²Department of Mathematics, Indian Institute of Science, Bangalore, India

Definition

Neurobiological data are often collected in the form of time series. Spectral analysis is the systematic study of time series in the frequency domain. In parametric spectral analysis, time series are treated as realizations of a stochastic process, and a model, typically an autoregressive model, is fit to the data, from which spectral quantities of interest such as power, coherence, and Granger causality spectra are then derived.

Detailed Description

We start by reviewing the basic concepts in the theory of stochastic processes which is the mathematical foundation of time series analysis. From this review one can clearly see that parametric

modeling of time series is not an ad hoc approach but arises naturally from the theory of stochastic processes.

Stochastic Processes

If only one variable is being recorded over time, the time series is said to be univariate. An example of a univariate EEG time series demonstrating the alpha rhythm is shown in Fig. 1. If multiple variables are being recorded at every time instant, the time series is said to be multivariate.

Since successive values in a time series are in general dependent, e.g., not white noise, one can attempt to predict the current value from past observations. If an exact prediction can be made, the time series is said to be deterministic. If the current value is only partly determined by the past values, the time series is said to be stochastic (Chatfield 2004). Almost all experimentally recorded time series data in neuroscience are stochastic in nature. Such time series can be described mathematically as realizations of discrete stochastic processes.

Consider first the univariate case. A univariate discrete stochastic process, denoted by $X(t)$, is a collection of random variables indexed by time t where t takes integer values. Mathematically, $X(t)$ is fully characterized by its joint probability distributions. In practice, the key properties of $X(t)$ can be characterized by mean, variance, and auto-covariance function, defined as $\mu(t) = E(X(t))$, $\sigma^2(t) = E((X(t) - \mu(t))^2)$, and $R_{xx}(t_1, t_2) = E((X(t_1) - \mu(t_1))(X(t_2) - \mu(t_2)))$, respectively. Here E stands for mathematical expectation, which, when analyzing actual data, can be replaced by sample averaging across multiple trials/realizations.

In case there is only one trial/realization available, one can appeal to the ergodic property of the process and replace the averaging across trials by averaging over time in this single trial/realization (Papoulis 1991). For this to be applicable, however, the process needs to be stationary and ergodic.

A class of stochastic processes that have found wide applications in real-world problems is the wide-sense stationary stochastic processes or simply (for the purposes of this entry) stationary processes (Chatfield 2004). For a stationary process, the mean and variance are both constant, i.e., $\mu(t) = \mu$, $\sigma^2(t) = \sigma^2$, and the auto-covariance function has the form $R_{xx}(t_1, t_2) = R_{xx}(\tau)$, where $\tau = t_2 - t_1$ is referred to as the time lag or simply lag. From these definitions, it is clear that $\sigma^2 = R_{xx}(0)$.

Because the auto-covariance function depends on the magnitude of the time series, making the comparison between different experimental conditions difficult, we typically normalize the auto-covariance function by $R_{xx}(0)$ to yield the autocorrelation function, $\rho_{xx}(\tau) = R_{xx}(\tau)/R_{xx}(0)$. The autocorrelation function measures the degree of linear dependence between $X(t)$ and $X(t + \tau)$ and has values between -1 and 1 . For stochastic processes encountered in applications, $\rho_{xx}(\tau) \rightarrow 0$ as $\tau \rightarrow \infty$, meaning that when the two random variables $X(t)$ and $X(t + \tau)$ are sufficiently separated in time, they are no longer correlated.

For a jointly stationary bivariate stochastic process $(X(t), Y(t))$, the cross-covariance function is defined as

$$R_{xy}(\tau) = E((X(t_1) - \mu_x)(Y(t_2) - \mu_y)) \quad (1)$$

where $\tau = t_2 - t_1$. Normalizing the cross-covariance function gives us the cross-correlation

Parametric Spectral Analysis, Fig. 1 EEG time series data from the occipital cortex of a human subject demonstrating the alpha rhythm

function which again takes values between -1 and 1 , that is,

$$\rho_{xy}(\tau) = R_{xy}(\tau) / \sqrt{R_{xx}(0)R_{yy}(0)} \quad (2)$$

$R_{xy}(\tau)$ characterizes the relation between the two time series and is an essential function for performing spectral analysis of bivariate stochastic processes. For a multivariate stochastic process $(X_1(t), X_2(t), \dots, X_n(t))$, the spectral analysis makes use of pairwise cross-covariance functions $R_{x_i x_j}(\tau)$ between $X_i(t)$ and $X_j(t)$, defined as $R_{x_i x_j}(\tau) = E\left((X_i(t_1) - \mu_{x_i})(X_j(t_2) - \mu_{x_j})\right)$. The corresponding cross-correlation function can also be similarly defined.

Spectral Analysis of Stochastic Processes

Spectral analysis is the systematic study of time series in the frequency domain. The three main quantities of interest are the power spectrum, coherence spectrum, and Granger causality spectrum. The power spectrum tells us how energy is distributed in different frequency bands, the coherence spectrum characterizes the degree of linear dependence between two time series at a given frequency, and the Granger causality spectrum quantifies the causal effects between two time series on a frequency-by-frequency basis (Ding et al. 2006).

For a univariate stationary stochastic process, the power spectrum is defined as the Fourier transform of the auto-covariance function defined in the previous section:

$$\begin{aligned} S_{xx}(f) &= \sum_{\tau=-\infty}^{\infty} R_{xx}(\tau) e^{-i2\pi f\tau} \\ &= R_{xx}(0) + 2 \sum_{\tau=1}^{\infty} R_{xx}(\tau) \cos(2\pi f\tau) \end{aligned} \quad (3)$$

where we have made use of the symmetry $R_{xx}(-\tau) = R_{xx}(\tau)$. Hence, $S_{xx}(f)$ is real and non-negative. Sometimes one is interested in the normalized power spectrum that is the Fourier transform of the autocorrelation function of the

process. An equivalent expression for the power spectrum is given by (Priestly 1981)

$$S_{xx}(f) = \lim_{N \rightarrow \infty} E(X(f)X^*(f))/N \quad (4)$$

where E denotes the mathematical expectation, $X(f)$ is the Fourier transform of $X(t)$, N denotes the length of data, and $*$ denotes the complex conjugate.

For a multivariate stochastic process $(X_1(t), X_2(t), \dots, X_m(t))$, an appropriate generalization of the power spectrum is the $m \times m$ spectral density matrix $S(f)$ defined as

$$S(f) = \begin{pmatrix} S_{x_1 x_1}(f) & \cdots & S_{x_1 x_{td}}(f) \\ \vdots & \ddots & \vdots \\ S_{x_{td} x_1}(f) & \cdots & S_{x_{td} x_{td}}(f) \end{pmatrix} \quad (5)$$

where $S_{x_i x_j}(f)$ is the cross-spectrum between $X_i(t)$ and $X_j(t)$ defined as the Fourier transform of the cross-covariance function $R_{x_i x_j}(\tau)$:

$$S_{x_i x_j}(f) = \sum_{\tau=-\infty}^{\infty} R_{x_i x_j}(\tau) e^{-i2\pi f\tau} \quad (6)$$

For $i \neq j$, $S_{x_i x_j}(f)$ is in general complex, yielding both amplitude and phase information. For $i = j$, $S_{x_i x_j}(f)$ reduces to the real (auto) power spectrum $S_{x_i x_i}(f)$ of the process $X_i(t)$. It can be shown that $S_{x_j x_i}(f)$ is the complex conjugate of $S_{x_i x_j}(f)$, and hence, $S(f)$ is a Hermitian matrix. As before, an equivalent expression for the cross-spectrum is given by (Priestly 1981)

$$S_{x_i x_j}(f) = \lim_{N \rightarrow \infty} E(X_i(f)X_j^*(f))/N \quad (7)$$

If we denote $(X_1(t), X_2(t), \dots, X_m(t))$ by the vector process $\mathbf{X}(t)$, the $m \times m$ spectral density matrix $S(f)$ is given by

$$S(f) = \lim_{N \rightarrow \infty} E(\mathbf{X}(f)\mathbf{X}^\dagger(f))/N \quad (8)$$

where $\mathbf{X}(f)$ denotes the Fourier transform of $\mathbf{X}(t)$ and $\mathbf{X}^\dagger(f)$ denotes the Hermitian conjugate of $\mathbf{X}(f)$.

A second quantity of interest in spectral analysis of stochastic processes is the spectral

coherence function between $X_i(t)$ and $X_j(t)$ (Chatfield 2004):

$$C_{x_i x_j}(f) = |S_{x_i x_j}(f)| / \sqrt{S_{x_i x_i}(f) S_{x_j x_j}(f)} \quad (9)$$

which sometimes is also called the ordinary coherence function or simply coherence function. This is the spectral analogue of the time-domain cross-correlation function.

A third quantity of interest in spectral analysis is Granger causality. The basic idea behind Granger causality can be explained in the time domain as follows. Consider two simultaneously recorded stationary time series. According to Wiener (1956), if the prediction of one time series is improved by incorporating the knowledge of a second one, then the second series is said to have a causal influence on the first. Granger (1969) later formalized the prediction idea in the context of linear regression models (see next section). Specifically, if the variance of the autoregressive prediction error of the first time series at the present time is reduced by inclusion of past measurements from the second time series, then the second time series is said to have a causal influence on the first one. Reversing the role of the two time series gives the causal influence in the opposite direction. The interaction discovered this way could be either reciprocal or unidirectional.

The derivation of the frequency-domain Granger causality, called Granger causality spectrum, is quite involved (see next section). The basic idea, however, is straightforward to appreciate. Again consider two stationary time series. Geweke (1982) showed that the spectral power at a given frequency f can be written as the sum of

two terms: $\text{power}(f) = \text{intrinsic power}(f) + \text{causal power}(f)$. The intrinsic power can be thought of as the power generated locally near the recording site, whereas the causal power term is the power brought about by the input from the other time series. The Granger causality at frequency f is then defined to be $I(f) = \ln(\text{power}(f)/\text{intrinsic power}(f))$. From this definition, it is clear that when the causal power is zero, namely, there is no causal input from the other time series, $I(f) = 0$. When the causal power is greater than zero, we have $I(f) > 0$, which indicates nonzero causal influence from the other time series at frequency f . This can be quantified more precisely and the relevant formulas are given in the next section.

For three or more time series, patterns of connectivity can become more intricate. To illustrate, consider three time series A, B and C. A pairwise analysis will not be able to distinguish the two patterns shown in Fig. 2. In this case the concept of conditional Granger causality becomes necessary (Geweke 1984; Chen et al. 2006; Ding et al. 2006).

Parametric Spectral Analysis Using Autoregressive Models

The mathematical foundation of parametric modeling of stationary time series is the Wold decomposition theorem (Papoulis 1985). For simplicity, consider the univariate case. According to the theorem, any zero-mean stationary process $X(t)$, if $\rho_{xx}(\tau) \rightarrow 0$ as $\tau \rightarrow \infty$, can be represented by the following infinite moving average (MA) model:

Parametric Spectral Analysis, Fig. 2 To distinguish the two different connectivity patterns, a conditional Granger causality analysis is required

$$X(t) = \sum_{j=0}^{\infty} b_j \varepsilon(t-j) \quad (10)$$

where $\varepsilon(t)$ is white noise and $\sum_{j=0}^{\infty} |b_j|^2 < \infty$. If the MA model is invertible, that is, if the zeros of the polynomial $p(z) = \sum_{j=0}^{\infty} b_j z^j$ all lie outside the unit circle, the model can be inverted to obtain an autoregressive (AR) model (Chatfield 2004):

$$X(t) = \sum_{j=0}^{\infty} a_j X(t-j) + \varepsilon(t) \quad (11)$$

Further, if the coefficients $a_j \rightarrow 0$ as $j \rightarrow \infty$, then the model can be truncated at finite order p to give the autoregressive model of order p (AR (p) model):

$$X(t) = a_1 X(t-1) + a_2 X(t-2) + \dots + a_p X(t-p) + \varepsilon(t) \quad (12)$$

Here $\varepsilon(t)$ is a white noise process with $\text{var}(\varepsilon(t)) = \sigma^2$.

The Wold decomposition theorem implies that the properties of stationary time series can be fully captured by autoregressive models. Parametric spectral analysis starts with fitting an AR(p) model to the experimental data. For a univariate process the simplest method to estimate $a_1, a_2, \dots, a_p, \sigma^2$ is given as follows (Chatfield 2004): Both sides of the AR equation are multiplied by $X(t-k)$ ($k = 0, 1, 2, \dots, p$), and the expectation is taken. This results in the following Yule-Walker equations (using the definition of auto-covariance function and its symmetry properties):

$$\begin{aligned} R_{xx}(k) &= a_1 R_{xx}(k-1) + a_2 R_{xx}(k-2) + \dots + \\ &\quad a_p R_{xx}(k-p); k = 1, 2, \dots, p; \\ R_{xx}(0) &= a_1 R_{xx}(1) + a_2 R_{xx}(2) + \dots + \\ &\quad a_p R_{xx}(p) + \sigma^2; k = 0 \end{aligned} \quad (13)$$

Here the auto-covariances are estimated from the data $\{x_n\}_{n=1}^N$ (which is now considered to be

a realization of the AR model) using the following expression:

$$R_{xx}(k) = \frac{1}{N} \sum_{n=k}^N x_n x_{n-k} \quad (14)$$

Substituting these estimates into the Yule-Walker equations, we get $p+1$ linear equations with $p+1$ unknowns. These can be solved for $a_1, a_2, \dots, a_p, \sigma^2$. The model order p can be estimated using the Akaike Information Criterion (Akaike 1971) or other criteria. For multiple realizations the quantity in Eq. 14 is estimated for each realization and averaged across realizations.

Once we have the AR representation of the time series data, the power spectrum $S_{xx}(f)$ can be obtained using Eq. 4. From Eq. 12, the Fourier transform $X(f)$ of $X(t)$ is given by

$$X(f) = (1 - a_1 e^{-i2\pi f} - a_2 e^{-i4\pi f} - \dots - a_p e^{-i2\pi p f})^{-1} \varepsilon(f) \quad (15)$$

where $\varepsilon(f)$ is the Fourier transform of the error term $\varepsilon(t)$. Defining a transfer function $H(f)$ as $(1 - a_1 e^{-i2\pi f} - a_2 e^{-i4\pi f} - \dots - a_p e^{-i2\pi p f})^{-1}$, the above equation can be rewritten as

$$X(f) = H(f) \varepsilon(f) \quad (16)$$

Substituting this in Eq. 4 and using the fact that

$$\begin{aligned} E(H(f) \varepsilon(f) \varepsilon^*(f) H^*(f)) / N \\ = H(f) E(\varepsilon(f) \varepsilon^*(f)) H^*(f) / N \end{aligned} \quad (17)$$

we finally get

$$S_{xx}(f) = H(f) \sigma^2 H^*(f) = |H(f)|^2 \sigma^2 \quad (18)$$

Here $\sigma^2 = E(\varepsilon(f) \varepsilon^*(f)) / N$ is the variance of the error term $\varepsilon(t)$.

As a concrete example, suppose that the given time series data can be modeled as an AR (1) process:

$$X(t) = a_1 X(t-1) + \varepsilon(t) \quad (19)$$

The transfer function $H(f)$ is given by

$$H(f) = (1 - a_1 e^{-i2\pi f})^{-1} \quad (20)$$

Hence,

$$\begin{aligned} S_{xx}(f) &= H(f) \sigma^2 H^*(f) \\ &= \sigma^2 / (1 - a_1 e^{-i2\pi f})(1 - a_1 e^{i2\pi f}) \\ &= \sigma^2 / (1 + a_1^2 - a_1 \cos(2\pi f)) \end{aligned} \quad (21)$$

The above expression can be evaluated at any arbitrary frequency, giving rise to a high-resolution power spectrum of the data. Further, one can analyze the power spectrum as a function of the system parameters (a_1 and σ^2 in this case) that can provide further insight into the system underlying the recorded data.

Next, consider a multivariate time series. It can be represented using a vector AR (VAR) process of order p :

$$\begin{aligned} \mathbf{X}(t) &= \mathbf{A}(1)\mathbf{X}(t-1) + \mathbf{A}(2)\mathbf{X}(t-2) \\ &\quad + \dots + \mathbf{A}(p)\mathbf{X}(t-p) + \mathbf{E}(t) \end{aligned} \quad (22)$$

Here $\mathbf{X}(t) = (X_1(t), X_2(t), \dots, X_m(t))^T$ is a multivariate process; $\mathbf{A}(i)$'s are $m \times m$ coefficient matrices, where m is the number of time series simultaneously measured; and $\mathbf{E}(t) = (\varepsilon_1(t), \varepsilon_2(t), \dots, \varepsilon_m(t))^T$ is the vector white noise process where $\varepsilon_i(t)$'s are serially uncorrelated over time but have a contemporaneous $m \times m$ covariance matrix given by $\mathbf{\Gamma}$. The diagonal elements of $\mathbf{\Gamma}$ represent the variances of the individual white noise processes, and the off-diagonal terms represent the cross-variances between these white noise processes.

Using a procedure similar to that followed for the univariate process, the coefficient matrices $\mathbf{A}(i)$'s and the error covariance matrix $\mathbf{\Gamma}$ can be estimated from the multivariate experimental time series data using the multivariate analogue of the Yule-Walker equations. To obtain the spectral density matrix, we first obtain the Fourier transform $\mathbf{X}(f)$:

$$\begin{aligned} \mathbf{X}(f) &= (1 - \mathbf{A}(1)e^{-i2\pi f} - \mathbf{A}(2)e^{-i4\pi f} - \dots - \\ &\quad \mathbf{A}(p)e^{-i2\pi pf})^{-1} \mathbf{E}(f) \end{aligned} \quad (23)$$

Substituting in Eq. 8, we obtain

$$S(f) = \mathbf{H}(f) \mathbf{\Gamma} \mathbf{H}^*(f) \quad (24)$$

where all quantities are now $m \times m$ matrices and the transfer function matrix $\mathbf{H}(f)$ is given by

$$\begin{aligned} \mathbf{H}(f) &= (1 - \mathbf{A}(1)e^{i2\pi f} - \mathbf{A}(2)e^{i4\pi f} - \dots - \\ &\quad \mathbf{A}(p)e^{i2\pi pf})^{-1} \end{aligned} \quad (25)$$

From the spectral density matrix in Eq. 24, the power spectra of all individual processes and the coherence spectra between processes can be readily derived according to the definitions given earlier.

In computing the Granger causality, consider fitting a bivariate AR model to X_i and X_j . The formula for the frequency-domain Granger causality from X_j to X_i at frequency f is (Ding et al. 2006).

$$\begin{aligned} I_{x_j \rightarrow x_i}(f) &= \ln \frac{S_{x_i x_j}(f)}{S_{x_i x_j}(f) - (\Gamma_{x_i x_j} - \Gamma_{x_i x_j}^3 / \Gamma_{x_i x_j}) |H_{x_i x_j}(f)|^2} \end{aligned} \quad (26)$$

The Granger causality spectrum from X_i to X_j is obtained by interchanging the indices i and j in the above expression. It is important to note that according to the approach outlined above, for Eq. 26 to apply, we fit a separate bivariate AR model to X_i and X_j for different combinations of i and j . This limitation has been overcome in a recent paper where it is shown that for the entire multivariate data set, only a single vector AR model fit is necessary. From the model, the Granger causality within any subset of the recorded data can be calculated (Wen et al. 2013).

To illustrate the multivariate framework, consider the following 3-variable ($m = 3$) AR (1) process:

$$\begin{aligned} X_1(t) &= \varepsilon_1(t) \\ X_2(t) &= X_1(t-1) + \varepsilon_2(t) \\ X_3(t) &= \lambda X_3(t-1) + X_1(t-1) + \varepsilon_3(t) \end{aligned} \quad (27)$$

where $|\lambda| < 1$ is a parameter and the noise terms $\varepsilon_i(t)$'s are assumed to be uncorrelated with one another and have variances σ_i^2 . The above equations can be written in matrix form as

$$X(t) = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 1 & 0 & \lambda \end{pmatrix} X(t-1) + E(t) \quad (28)$$

Here the noise vector $E(t)$ has a diagonal covariance matrix $\Gamma = \text{diag}(\sigma_1^2, \sigma_2^2, \sigma_3^2)$ since the individual noise terms are uncorrelated with one another.

Taking Fourier transforms on both sides and simplifying, we get

$$\begin{pmatrix} 1 & 0 & 0 \\ e^{-i2\pi f} & 1 & 0 \\ e^{-i2\pi f} & 0 & 1 - \lambda e^{-i2\pi f} \end{pmatrix} X(f) = E(f) \quad (29)$$

Thus, $X(f) = H(f)E(f)$ where the transfer function matrix $H(f)$ is given by

$$\begin{aligned} H(f) &= \begin{pmatrix} 1 & 0 & 0 \\ e^{-i2\pi f} & 1 & 0 \\ e^{-i2\pi f} & 0 & 1 - \lambda e^{-i2\pi f} \end{pmatrix}^{-1} \\ &= \begin{pmatrix} 1 & 0 & 0 \\ -e^{-i2\pi f} & 1 & 0 \\ -e^{-i2\pi f} & 0 & \frac{1}{1 - \lambda e^{-i2\pi f}} \end{pmatrix} \end{aligned} \quad (30)$$

Substituting the expressions for $H(f)$ and Γ in Eq. 8, we get the spectral density matrix to be

$$S(f) = \begin{pmatrix} \sigma_1^2 & -e^{i2\pi f} \sigma_1^2 & \frac{(\lambda - e^{i2\pi f}) \sigma_1^2}{(1 + \lambda^2 - 2\lambda \cos(2\pi f))} \\ -e^{i2\pi f} \sigma_1^2 & \sigma_1^2 + \sigma_2^2 & \frac{(1 - \lambda e^{-i2\pi f}) \sigma_1^2}{(1 + \lambda^2 - 2\lambda \cos(2\pi f))} \\ \frac{(\lambda - e^{i2\pi f}) \sigma_1^2}{(1 + \lambda^2 - 2\lambda \cos(2\pi f))} & \frac{(1 - \lambda e^{i2\pi f}) \sigma_1^2}{(1 + \lambda^2 - 2\lambda \cos(2\pi f))} & \frac{\sigma_1^2 + \sigma_3^2}{(1 + \lambda^2 - 2\lambda \cos(2\pi f))} \end{pmatrix} \quad (31)$$

The diagonal terms represent the auto power spectrum of the three processes comprising the above VAR model, and the off-diagonal terms represent the cross-spectrum between these processes. As before, we can examine the behavior of these spectra as a function of the system parameters.

From the spectral density matrix in Eq. 31, we can compute the pairwise coherences using Eq. 9:

$$\begin{aligned} C_{x_1 x_2}(f) &= \frac{|S_{x_1 x_2}(f)|}{\sqrt{S_{x_1 x_1}(f) S_{x_2 x_2}(f)}} = \frac{\sigma_1}{\sqrt{\sigma_1^2 + \sigma_2^2}} \\ C_{x_1 x_3}(f) &= \frac{|S_{x_1 x_3}(f)|}{\sqrt{S_{x_1 x_1}(f) S_{x_3 x_3}(f)}} = \frac{\sigma_1}{\sqrt{\sigma_1^2 + \sigma_2^2}} \\ C_{x_2 x_3}(f) &= \frac{|S_{x_2 x_3}(f)|}{\sqrt{S_{x_2 x_2}(f) S_{x_3 x_3}(f)}} \\ &= \frac{\sigma_1^2}{\sqrt{(\sigma_1^2 + \sigma_2^2)(\sigma_1^2 + \sigma_2^2)}} \end{aligned} \quad (32)$$

In this simple case, all the pairwise coherences happen to be constant independent of frequency.

We can also obtain the pairwise Granger causalities using Eq. 26:

$$\begin{aligned} I_{1 \rightarrow 2}(f) &= \ln \left(\frac{\sigma_1^2 + \sigma_2^2}{\sigma_2^2} \right) \\ I_{1 \rightarrow 3}(f) &= \ln \left(\frac{\sigma_1^2 + \sigma_2^2}{\sigma_2^2} \right) \end{aligned} \quad (33)$$

The other pairwise Granger causalities are all zero.

Parametric Versus Nonparametric Spectral Analysis

We conclude by contrasting parametric spectral analysis with nonparametric spectral analysis. In nonparametric spectral analysis, the desired spectral quantities are obtained directly from the data using Fourier or wavelet transforms, in conjunction with various windowing techniques ranging from the simple (e.g., the periodogram method) to the more advanced (e.g., the multitaper method) (Percival and Walden 1993). The main advantage of the nonparametric spectral methods is that they are intuitive and have no need to go through an intermediate layer of data modeling. The disadvantages include limited frequency resolution and vulnerability to estimation bias when the data length is short. It used to be the case that directional measures such as the Granger causality could not be obtained from Fourier- or wavelet-based analysis. This limitation has recently been overcome via the introduction of spectral factorization methods (Dhamala et al. 2008a, b).

The advantages of the parametric method include the ability to resolve spectral quantities to arbitrarily high resolution in the frequency domain, smoother spectral estimates, being less vulnerable to the shortness of data windows, and the ability to generate the Granger causality spectra. The disadvantages include occasional difficulties in obtaining an optimal model that fits the data.

Definition

Paraspinal magnetic and electrical stimulation target deep neural structures within the vertebral canal and in between neighboring vertebrae from a distance of several centimeters, with either magnetic coils or skin electrodes. The principal mechanism of stimulation at the neuronal level is the same for magnetic and electrical stimulation and is given by the induced electric field component or, in an equivalent way, the electric potential, generated along the anatomical path of the nerve fibers. Yet the generation of electric fields by electromagnetic induction or electrical stimulation bases on different physical principles, and the currents generated differ substantially, both as a function of time (pulse shape) and space (distribution in the body tissues). Induced ionic tissue currents secondary to externally applied, time-varying magnetic fields enter the spine

predominantly from its sides, while the currents generated by transcutaneous electrical stimulation penetrate it mainly from its back (or front). The motor fibers within the spinal nerves and anterior rootlets are the common targets of paraspinal magnetic stimulation. Different techniques of transcutaneous electrical stimulation either excite the motor fibers in the spinal nerves/anterior rootlets or selectively activate the sensory fibers within the posterior roots/rootlets. Furthermore, longitudinal tracts within the white matter of the spinal cord can be directly activated by high-voltage electrical stimulation. Neural networks of the spinal cord gray matter are exclusively activated transsynaptically, e.g., through the inputs provided by electrically stimulated sensory fibers. The applications of paraspinal magnetic and transcutaneous electrical stimulation depend on the stimulated neuroanatomy. They include the neurodiagnostic assessment of the functional integrity of lower motoneurons, neurophysiological studies of spinal cord neural networks, the generation of patterned muscle contractions for useful bodily functions, and neuromodulation applications.

Detailed Description

Magnetic and transcutaneous electrical stimulation applied over the spine and spinal cord produce electric fields by different physical principles. Paraspinal magnetic stimulation generates continuous, ionic current flows that close on themselves following the principles of electromagnetic induction. The current flow is largely constrained to planes parallel to the surface of the volume conductor in contact with the magnetic coil, i.e., to the back. Hence, the induced currents are mainly circular and oriented parallel to the frontal (coronal) plane. In transcutaneous electrical stimulation, the potential difference between the skin electrodes during a stimulation pulse causes current to flow from the anode to the cathode via the intermediate anatomical structures. Close to the paraspinal electrodes and also within the spine, current flows have directions perpendicular to the frontal plane. The current

flows generated by paraspinal magnetic and electrical stimulation are thus very unlike.

Within the human body, the current flow is shaped by the electrical tissue properties and the numerous conductivity boundaries. The bony structures of the spine, owing to their high electrical resistance, have a considerable influence on the produced currents. Yet, unlike the brain, the spinal roots and spinal cord are not completely enclosed by bony material. The electrical resistance across the spine is reduced by soft tissues, including ligaments and disks, between neighboring vertebrae (Fig. 1). Structures within the “openings” of the spine have better electrical conductivities than the bones as well. The longitudinal, centrally located vertebral canal contains the spinal cord and spinal roots. It is formed by the vertebrae and, in the intervertebral spaces, by the ligaments. The intervertebral foramina (or neuroforamina) are the bilateral openings between every pair of vertebrae that allow for the exits of the spinal roots/nerves from the vertebral canal. The sacral canal is the continuation of the vertebral canal within the sacral bone of the pelvis. Its openings for the sacral roots of the cauda equina, the anterior sacral foramina, have a posteroanterior orientation.

A further important influence on the immediate stimulation effects is given by the fiber paths of the neural target structures, i.e., the alterations of their spatial orientation with respect to the electric field. Cervical and upper thoracic roots course laterally or slightly downward from the spinal cord to the respective intervertebral foramina. There, they have short, upwardly directed segments. Lumbar and sacral roots have a sharp, caudally directed bend as they exit the spinal cord, followed by a longitudinal component through the cauda equina. The roots then exit the canal at angles between 20° and 40° to the longitudinal axis, with a rather mediolateral orientation at the intervertebral foramina and a posteroanterior orientation at the anterior sacral neuroforamina.

General Principles of Nerve Stimulation

The substructure of a neuron most excitable by external stimulation is the myelinated axon. In magnetic stimulation, the activation of the axon is not directly caused by the magnetic field but by the electromagnetically induced electric field. The principal mechanism of neural stimulation is thus the same for paraspinal magnetic and electrical

Paraspinal Magnetic and Transcutaneous Electrical Stimulation, Fig. 1 Geometry of the human spine. While the bony structures appear quite

massive in the three-dimensional representation, the section shows the extent of soft tissues with better electrical conductivities. The anterior to posterior direction is from left to right. (Reproduced from Xia et al. (2009) with permission from Springer Science and Business Media)

stimulation. The electric field $\mathbf{E}$ is a vector field given in V/m. Equally, the electric potential Φ , a scalar field measured in V, describes the stimulation effects upon the neural structures. Their relation is given by $\mathbf{E} = -\nabla\Phi$. The stimulation-generated electric field/potential distribution causes ionic currents to flow within the electrically conducting anatomical structures. A fraction of the current passes the nerve fiber membranes, thereby producing local depolarizations and hyperpolarizations. Depolarization of the membrane to a threshold level generates an action potential that normally propagates in both directions along the nerve fiber. Low excitation thresholds result from sudden changes of the electric field component or of the potential distribution along the axon's anatomical path. More precisely, the strongest depolarization is produced at the peak of the second-order spatial difference of the electric potential along the nerve fiber (Rattay 1999 and see entry ► [“Finite Element Modeling for Extracellular Stimulation”](#)). Equivalently, the depolarization is proportional to the negative-going, first-order spatial difference of the electric field tangential to the fiber path. Effective stimulation of a large-diameter myelinated axon requires changes of the electric potential across distances covering neighboring nodes of Ranvier, i.e., distances of few millimeters. Along such distances, large values of the second-order spatial difference of the electric potential can be present even in a non-focal electric field, if an axon (i) alters its spatial orientation within the field or (ii) passes electrical inhomogeneities of the tissues surrounding it. Considerable inhomogeneities arise across the intervertebral foramina, as well as at the interface between the spinal rootlets and the spinal cord (sudden change in conductance between the cerebrospinal fluid and the spinal cord). At the same sites, these inhomogeneities are added to by the alterations of the spatial orientation of the sensory and motor fibers, particularly those of the lumbar and sacral roots. Due to these low-threshold sites, deep neural structures can be stimulated, and the depolarization sites are predictable in spite of the distant stimulation and widespread fields.

Biophysics of Paraspinal Magnetic and Transcutaneous Electrical Stimulation

Paraspinal Magnetic Stimulation

Magnetic stimulation follows the fundamental principles of electromagnetic induction. A brief electric current pulse flowing in a coil of wires creates a time-varying magnetic field. The magnetic field passes unimpeded through biological tissues with low electrical conductivity and gives rise to an electric field. Within the electrically conductive tissues of the human body, the electric field causes ionic current flows. These induced secondary currents are circular, flowing in the opposite direction to the primary coil current, and are affected by the inhomogeneous and anisotropic electrical tissue properties. A principal difference between magnetic and transcutaneous electrical stimulation in the activation of deep neural structures is that these secondary currents do not flow from the body surface to the target but are induced without localized electrical “sources” or “sinks” within the body volume. The relatively low current densities at the skin below the coil result in a reduced excitation of nerve endings that may otherwise cause discomfort.

The magnetic field (i.e., the magnetic flux density $\mathbf{B}$) is a vector field given in tesla ($1 \text{ T} = 1 \text{ Vs/m}^2$). The magnetic field lines are closed loops, cross the coil plane at perpendicular angles, and curve outward from the coil. At the center of a round coil, maximum magnetic fields of 1–2.5 T are generated. The effective depth of magnetic stimulation is limited by the rapid (exponential) decay of the induced electric field along a line perpendicular to the coil's plane. As a function of time, the magnetic field exhibits the same waveform as the coil current. The current waveform and the current direction within the coil are thus critical electrical characteristics determining the stimulation effects. Monophasic (or near-monophasic) and biphasic (or damped oscillatory) waveforms are produced by conventional magnetic stimulators, usually with rise times of 50–200 μs and durations of 100–1000 μs . The monophasic coil current waveform has a rapid rise time and a slower decay to zero. The current producing the magnetic field flows in one

direction of the coil only. Thus, by flipping the coil, the direction of the secondary currents induced in the human tissues is reversed, which generally has an influence on the thresholds of the neural target structures. The waveform of a biphasic coil current pulse is a decaying full cycle of a sine wave (Fig. 2a, dotted line). With the secondary currents induced in either direction, the determination of the site of stimulation may become more difficult.

Like the induced electric field $\mathbf{E}$, the secondary tissue current $\mathbf{J}$ (current density in A/m^2) is a vector field, and $\mathbf{J} = \sigma \mathbf{E}$ (σ is the electrical conductivity given in Siemens per meter, S/m). During a stimulation pulse, $\mathbf{E}$ and $\mathbf{J}$ have the same time courses that follow the first time derivative of the primary coil current (Fig. 2a, solid line). The

stronger the applied magnetic field and the faster the field changes (first time derivative of the magnetic flux density, $d\mathbf{B}/dt$), the greater the current induced within the body tissues.

Basic principles of the spatial electric field and current distribution induced by magnetic stimulation are derived from controlled experimental conditions and simplified models (Cohen and Cuffin 1991; Maccabee et al. 1991, 1996; Miranda 2005). The electromagnetically induced tissue current is continuous and closes on itself within the volume conductor. Enclosed are regions where the current flows are zero ("null points"). The spatial distributions of the electromagnetically induced electric fields are different for different coil geometries. Standard coils are circular (round) coils and figure-8 (double

Paraspinal Magnetic and Transcutaneous Electrical Stimulation, Fig. 2 Pulse shapes of paraspinal magnetic and electrical stimulation. (b and c) show the voltage across a resistor produced by the Digitimer D180 (decay constant set at 50 and 100 μs) and the Digitimer D185, respectively, both applied in high-voltage electrical stimulation. (d and e) are the

biphasic pulses of a current-controlled and a voltage-controlled stimulator, respectively, as used for transcutaneous spinal cord stimulation. *Solid lines* are currents through and *dashed lines* are voltages across an individual, measured at the electrodes during stimulation. The scaling of the ordinates is arbitrary; the figures compare the stimulation voltages/generated currents as a function of time for the various stimulation techniques. Different timescales in (a–c) versus (d–e)

circular, butterfly) coils. A figure-8 coil consists of two circular (or D-shaped) coils with opposite current direction placed side by side. In a homogeneous volume conductor, a circular coil held flat to its (planar or spherical) surface induces an annular current flow opposite in direction to the primary coil current and in planes parallel to the air-conductor interface (Fig. 3a). The current density is maximal beneath the windings of the coil and rapidly falls off toward the coil center, while the decay when moving outward from the coil is more gradual. The result is a broad, very non-focal distribution of the induced currents. Some directional sensitivity of the induced current distribution can be achieved by a figure-8 coil (Fig. 3b). The current loops superimpose maximally under the region of the long axis of the junction of the two coil wings. Positioning the junction above a target area produces a maximum current flow through it with currents of lower density returning in circles on both sides.

The suppression of electric field components perpendicular to the volume conductor's surface in contact with the magnetic coil is due to boundary effects. An electric field component perpendicular to a planar infinite boundary is not

induced, regardless of the coil type or orientation (the normal component of the current flow at the tissue-air boundary must be zero). Similarly, when paraspinal magnetic stimulation is applied, the vectors of the electric field and current density are initially parallel to the boundary of the back as well, and thus the currents induced within the volume conductor are predominantly parallel to the frontal plane. For further information on the biophysics of magnetic stimulation, see Miranda (2005), Epstein (2008), Riehl (2008), and Sommer (2008).

The influence of the spine on the electric field distribution induced by magnetic stimulation was described using human cervical-thoracic and lumbosacral spine segments immersed in a saline-filled container (Maccabee et al. 1991, 1996). The electric fields induced by a circular coil and a large figure-8 coil were measured within the intervertebral foramina, the vertebral canal, and the sacral canal. The direction of the electric field across the intervertebral foramina and within the vertebral canal is similar to that expected in a homogeneous volume conductor. Thus, induced currents enter and exit the spine from its sides. Due to "current-tunneling" effects, the maximum

Paraspinal Magnetic and Transcutaneous Electrical Stimulation, Fig. 3 Electric fields induced by (a) a circular and (b) a figure-8 magnetic coil oriented flat against the bottom surface of a cylindrical tank filled with isotonic saline. The electric field distributions are represented by current arrow diagrams in a plane parallel to the bottom

surface; magnitudes and directions are derived from measurements using a coaxial cable probe. The arrows are equally spaced, and the relative current densities are indicated by the size of each arrow. (Reproduced from Maccabee et al. (1991) with permission from Elsevier Scientific Publishers)

electric field intensities produced in and near an intervertebral foramen are more than two times larger than within the vertebral canal. More importantly, the first-order spatial difference of the electric field across the intervertebral foramen is more than 10 times larger than along the vertebral canal. Accordingly, paraspinal magnetic stimulation preferentially excites fibers within the spinal roots/nerves at the intervertebral foramina (Ugawa et al. 1989). Large-intensity electric field components are induced in several neighboring intervertebral foramina simultaneously. Depending on the coil geometry and orientation with respect to the spine, current flow through the left and right foramina of the same intervertebral level can have the same or opposite directions. Moreover, the direction of current flow through the intervertebral foramina along a given side of the spine can change, with null points in between (e.g., circular coil positioned with its center directly over the spine). While the mediolateral orientation of the intervertebral foramina is ideally channeling the induced electric field, locally concentrating the induced current, such “hot spots” for stimulation are not produced at the anterior sacral foramina with their anteroposterior orientation. Stimulation of neural structures within the vertebral canal requires anatomical conditions that considerably influence the first-order spatial difference of the electric field tangential to the fiber paths. Such inhomogeneity arises at the interface between nerve rootlets and the spinal cord, where the electrical conductivity of the volume conductor as well as the spatial orientation of the fibers with respect to the generated electric field changes abruptly.

Paraspinal Transcutaneous Electrical Stimulation

In paraspinal transcutaneous electrical stimulation, a minimum of two electrodes are placed over the body surface with a configuration to produce tissue currents that partially pass the neural target structures. During a stimulation pulse, a potential difference between the electrodes is built up that causes ionic tissue currents to flow from the anode to the cathode. The current flows according to the electrical conductivities of the tissues and spreads due to the repulsive forces

exerted between like charges. The basic principles of the spatial electric field and current distribution generated by paraspinal transcutaneous electrical stimulation are derived from computer models (Ladenbauer et al. 2010; Szava et al. 2011). All currents generated within the volume conductor need to pass the electrode-skin interfaces and flow through several centimeters of low-conductivity tissues to reach the neural targets. High current densities develop directly below the skin electrodes, and less than 10% of the produced current flows through the volume containing the spinal roots and spinal cord. Close to the stimulating electrodes, the current flow is directed perpendicularly to the electrode-skin interface. Most of the current flows around the spine, while some current enters/exits the spine mainly via the soft tissues with better conductivities in a direction perpendicular to the frontal plane. With symmetrically midline-positioned electrodes, current penetration from the sides into the spine is minimal. The current direction within the spine and vertebral canal also depends on the placement of the skin electrodes. With cathode and anode placed longitudinally over the back, most of the current flows tangentially to the spinal cord in the vertebral canal, mainly concentrated in the better-conducting cerebrospinal fluid. Moreover, close to the vertebral levels of the paraspinal cathode and anode positions, currents enter/exit the spine in opposite directions. With one electrode over the back and one anteriorly placed (e.g., over the abdomen), the current enters and exits the spine and the vertebral canal in one direction, mainly perpendicularly to the frontal plane.

The stimulation of deep neural structures is made possible by the inhomogeneities of the electrical tissue properties around and within the spine and the bends of the fiber paths of the target neurons. These anatomical influences considerably reduce the thresholds of some neural structures at localized sites and thus create hot spots for external electrical stimulation. Details and biophysical principles are presented in Minassian et al. (2011) and in the entry ► [“Finite Element Models of Transcutaneous Spinal Cord Stimulation.”](#) Depolarization sites partially depend on the method of electrical stimulation applied, as well as the vertebral level of stimulation. Hot spots for

stimulation predicted by computer modeling are at the interface of the posterior rootlets and the spinal cord (selective stimulation of sensory fibers) and at the distal segments of the posterior and anterior roots close to the intervertebral foramina (Ladenbauer et al. 2010; Danner et al. 2011). In high-voltage stimulation, the most proximal segments of the anterior rootlets at their exits from the spinal cord can be locally targeted as well (de Noordhout et al. 1988).

Two stimulation methods, referred to as “high-voltage (paraspinal) electrical stimulation” and “transcutaneous spinal cord stimulation,” are described. They target different neural structures and differ in the time parameters of stimulation (pulse shape and duration) as well as the spatial arrangement of the stimulating electrodes (size and placement).

High-voltage electrical stimulation was primarily designed for supramaximal stimulation of the motor roots as close to their exits from the spinal cord as possible. It uses stimulators as employed in transcranial electrical stimulation of the motor cortex, where high-intensity pulses are applied to penetrate the cranium. Two stimulators are commonly used, the Digitimer D180 and D185 (Digitimer Ltd., Hertfordshire, England, UK). The D180 produces a spike-like pulse with a very fast rise time of 5 μ s and a decay constant of either 50 μ s or 100 μ s and has a maximal output of 750 V (Fig. 2b). The D185 produces a rectangular-like pulse of 50- μ s width and has a maximal output of 1000 V (Fig. 2c). Stimuli are delivered through electrodes with active areas of the cathode smaller than 1 cm². With a midline-positioned cathode over the target vertebral level, the anode can be positioned 2–3 vertebral segments rostrally (“conventional longitudinal median montage,” Rossini et al. 1994; Troni et al. 1996). More distant anodes, e.g., over the abdomen (“dorsoventral montage,” Troni et al. 1996) in the stimulation of lumbosacral roots, produce responses at lower intensities.

Transcutaneous spinal cord stimulation was designed to noninvasively stimulate similar sensory structures as with epidural implants over the lumbar spinal cord (Minassian et al. 2007; Ladenbauer et al. 2010). It uses equipment similar to that in functional electrical stimulation (FES) of

paralyzed muscles or in therapeutic transcutaneous electrical nerve stimulation (TENS). By using skin electrodes with large surface areas and applying longer pulse widths (Fig. 2d, e), the thresholds of the targeted neural structures are considerably reduced. This allows using conventional stimulators for continuous stimulation at a fixed frequency for a longer period of time. Stimulators that produce maximum stimulus intensities of 60–100 V (voltage-controlled stimulators) or 120–200 mA (current-controlled stimulators) are appropriate. The large electrodes and moderate stimulation intensities further reduce discomfort (Roy et al. 2012). When stimulation is applied in a continuous mode for neuromodulation applications, the output must be charge balanced to reduce the likelihood of skin damage or irritation. The electrode setups utilize paraspinally placed stimulating electrodes and anteriorly placed reference electrodes. The method described in Minassian et al. (2007) uses a pair of round electrodes (diameter 5 cm) over the paraspinal skin with a pair of rectangular reference electrodes (8 $\times$ 13 cm each) covering the lower abdomen (Fig. 4). The exact electrode dimensions are not essential, yet relatively large reference electrodes ensure a stronger stimulating effect over the spine. Symmetrical, biphasic rectangular pulses (1 ms width per phase) delivered by a constant-voltage stimulator require low stimulus intensities. The paraspinal electrodes act as cathode when the polarity of the biphasic stimulus pulse is changed at the edge between its first and second phase (Fig. 2e), and neural elements are stimulated at this abrupt change of polarity. Alternative stimulation setups use reference electrodes placed over the iliac crests (Dy et al. 2010; Roy et al. 2012). For further details, see Minassian et al. (2011).

Stimulated Neural Structures, Site of Excitation, and Evoked Muscle Responses

Paraspinal Magnetic Stimulation

Magnetic stimulation over the cervical and lumbar spinal cord normally excites motor fibers within the anterior roots/spinal nerves at the intervertebral foramina (Ugawa et al. 1989). The

Paraspinal Magnetic and Transcutaneous Electrical Stimulation, Fig. 4 Transcutaneous spinal cord stimulation. (a) Drawings of the stimulation and reference

electrodes over the back and abdomen, respectively, and (b) of their positions with respect to the spine and spinal cord

evoked responses, recorded with surface electrodes as compound muscle action potentials (CMAPs) from the respective muscles, are hence M-waves. The onset latencies of these M-waves are shorter than the total peripheral motor conduction time by the segment from the anterior horn cells to the intervertebral foramen. These onset latencies remain constant when moving the coil over the spine for some centimeters in rostral or caudal direction to the lowest-threshold site. Only with maximum stimulation, the sites of excitation along the motor fibers may migrate distally beyond the intervertebral foramina. Paraspinal magnetic stimulation does not allow for reliable supramaximal stimulation. Maximum attainable response amplitudes range from 10% to 90% of the maximal peripheral nerve M-wave. Large-amplitude responses cannot be obtained simultaneously in multiple muscles of a limb from a single stimulation site. Custom-made, large circular coils can be used to overcome some of these limitations (Matsumoto et al. 2009a). M-waves in response to magnetic stimulation over the cervical-thoracic spine are described in various C5-T1 innervated muscles of the shoulder (deltoid), arm (biceps, brachioradialis, extensor digitorum), and hand (thenar and hypothenar muscle groups). These responses have the lowest thresholds and are largest when the secondary tissue current is directed over the intervertebral foramina of the target motor roots and flows from

the midline toward the side. Such stimulation favors unilateral excitation (Mills et al. 1993). For details on coil placements, see Ugawa et al. (1989), Mills et al. (1993), Rossini et al. (1994), and Sandbrink (2008). Stimulation over the mid-thoracic spine (T7-T9) evokes M-waves in the abdominal and intercostal muscles (Chokroverty et al. 1995). Magnetic stimulation over the lumbosacral spine elicits M-waves in the muscles of the upper and lower leg and the foot (e.g., quadriceps femoris, tibialis anterior, gastrocnemius, extensor digitorum brevis, flexor hallucis brevis, and abductor hallucis). For stimulating lumbar roots exiting the spine through the intervertebral foramina, the induced current can be concentrated through these hot spots of stimulation when oriented from side to side, and motor fibers are activated at the most distal portion of the cauda equina. The situation is different for muscles with motor roots exiting from the anterior sacral foramina. With the coil held over the sacral bone, the sacral roots are stimulated in the most distal portion of the cauda equina, as suggested by the very short onset latencies of the M-waves, but the exact site of stimulation is not completely clear (Maccabee et al. 2011). For details, see Ugawa et al. (1989) and Maccabee et al. (1996).

A second localized activation site of the motor fibers is within the vertebral canal at the interface between the spinal cord and the anterior rootlets. Activation at these proximal sites is reported for

magnetic stimulation over the lumbosacral spinal cord and requires large coils and the induced tissue currents to be directed rostrally (Maccabee et al. 1996, 2011; Matsumoto et al. 2009b). Thresholds at these proximal hot spots are higher than those at the intervertebral foramina. M-waves elicited proximally are similar in appearance to those elicited in the distal cauda equina, but the onset latencies are longer by 1.9 ms for the vastus medialis, 2.3 ms for the tibialis anterior, and 3.5 ms for the abductor hallucis (Maccabee et al. 1996). The straight, relatively long intrathecal segments of the lumbosacral motor fibers between their two low-threshold sites are normally not activated by magnetic stimulation.

Apart from the M-wave, a second type of muscle response can be evoked by magnetic stimulation, i.e., a CMAP constituted of two partially superimposed response components, an M-wave and a later response with electrophysiological characteristics similar to the H-reflex (Maccabee et al. 1996). Such composite responses are only evoked in few lower limb muscles and with stimulation over the distal cauda equina. The H-reflex is a monosynaptic reflex usually initiated by the electrical stimulation of Ia afferent fibers from muscle spindles at the posterior knee and recorded from the soleus muscle. A “pure” H-reflex without contamination by a preceding M-wave is normally not obtained by magnetic stimulation.

There is no evidence for the direct electrical stimulation of neural structures within the spinal cord white or gray matter by magnetic coils. Paresthesias (tingling sensations) or motor responses in the lower limbs are not evoked with magnetic stimulation over the cervical-thoracic spine (Ugawa et al. 1989). Thus, stimulation of myelinated, large-diameter, and relatively superficially located fibers within long tracts of the spinal cord white matter does not occur. It is estimated that a sevenfold increase of the maximum output of conventional magnetic stimulators would be required for their excitation (Maccabee et al. 1991). Consequently, the direct electrical stimulation of the spinal cord gray matter interneurons or neural networks, which would require even higher thresholds, is considered impossible.

High-Voltage Electrical Stimulation

The principal neural targets of high-voltage paraspinal electrical stimulation are the motor roots, and the evoked responses are M-waves (Rossini et al. 1994). Midline-positioned electrodes activate muscles bilaterally and symmetrically (i.e., at similar thresholds). High-voltage electrical stimulation over the cervical spine excites motor fibers innervating the upper limb muscles. The site of excitation is within the anterior roots/spinal nerves close to the respective intervertebral foramina, estimated 2–4 cm distal to the anterior horn cells (Mills and Murray 1986). The latencies of the M-waves evoked in the upper limb are about 1.2–1.6 ms shorter than the total peripheral motor conduction time (Mills and Murray 1986; Rossini et al. 1994). At moderate stimulus intensities, the response latencies remain unchanged when moving the electrode in vertical or horizontal direction for several centimeters. With the cathode over the T1 vertebra and the anode over the C5 vertebra, all motor roots to the upper limb muscles are recruited (Rossini et al. 1994). A more selective stimulation is achieved by placing the cathode over the vertebra of the corresponding exit level of the target motor root, with a distant anode over the contralateral shoulder (Ugawa et al. 1989). High-voltage electrical stimulation over the cervical enlargement allows for supramaximal stimulation of the cervical motor roots, with maximum upper limb muscle responses at 250–300 V.

For stimulation over the lumbosacral spine, two low-threshold sites for the activation of the motor fibers can be distinguished. Cathodes over T11-L1 vertebral levels, corresponding to the level of the lumbosacral spinal cord, excite the motor fibers within the anterior rootlets at their exits from the spinal cord (de Noordhout et al. 1988; Troni et al. 2011). Cathodes over L3-S1 vertebral levels activate the anterior roots/spinal nerves close to the respective intervertebral foramina (de Noordhout et al. 1988). At very strong stimulus intensities, the motor roots may be activated at some site in between these low-threshold sites (de Noordhout et al. 1988). M-waves in the lower limbs have similar CMAP shapes when elicited from both low-threshold

sites, but with the more distal stimulation, the onset latencies decrease by 1.4 ± 0.6 ms for the quadriceps, 2.4 ± 1.2 ms for the tibialis anterior, and 3.0 ± 1.0 ms for the extensor digitorum brevis (de Noordhout et al. 1988). With the cathode placed midline over the spine and the anode over the contralateral iliac crest, threshold intensities for CMAPs elicited in the lower limb muscles range from 225 to 450 V, and maximum responses are obtained at 450–600 V (de Noordhout et al. 1988; Ugawa et al. 1989). A single stimulus pulse applied from a fixed stimulation site can generate simultaneous supramaximal stimulation of the L3-S1 motor roots when using a dorsoventral montage (Troni et al. 2011).

Both a direct M-wave and a later response similar to the H-reflex can be evoked in the soleus by high-voltage electrical stimulation over the T11-S1 vertebral levels (de Noordhout et al. 1988; Troni et al. 1996), hinting on the activation of large-diameter proprioceptive fibers in addition to motoneuron axons. The difference between the M-wave and reflex-response latencies is 1.2 ± 0.2 ms for stimulation over the lumbosacral spinal cord and 5.4 ± 0.9 ms for stimulation of the distal cauda equina (Troni et al. 1996). With the elicitation of maximal M-waves, the reflex component is canceled.

Maximal high-voltage electrical stimulation over the cervical-thoracic spine evokes low-amplitude responses in some lower limb muscles innervated by distant lumbar and upper sacral spinal cord segments (Mills and Murray 1986; Taylor and Gandevia 2004). In the relaxed muscle, they normally attain amplitudes $<10\%$ of the maximum M-wave evoked by electrical peripheral nerve stimulation. The thresholds of these responses are 300–750 V and are always higher than those of the M-waves evoked by the stimulation of the nearby spinal nerves. The distant responses result from the electrical stimulation of descending corticospinal tracts of the spinal cord white matter and the transsynaptic activation of lumbosacral motoneurons innervating the lower limb muscles. They are thus motor-evoked potentials and due to the stimulation of similar populations of corticospinal axons as activated by transcranial stimulation of the motor cortex

(Martin et al. 2008). The exact site of stimulation along the corticospinal axons below the stimulating paraspinal electrodes is not defined.

Transcutaneous Spinal Cord Stimulation

The targeted neural structures of transcutaneous spinal cord stimulation are sensory fibers projecting into the spinal cord. For stimulation over the T11-T12 spinous processes, overlying the lumbar spinal cord, the low-threshold sites are at the entries of the posterior rootlets into the spinal cord (Minassian et al. 2011). The evoked responses result from the electrical stimulation of Ia muscle spindle afferents and the subsequent monosynaptic activation of motor fibers innervating the lower limb muscles. According to their initiation and recording sites, they were termed posterior root-muscle (PRM) reflexes (Minassian et al. 2007). Alternative terminologies were suggested (Dy et al. 2010; Roy et al. 2012). A single pulse can consistently activate L2-S2 posterior root fibers bilaterally and thus evoke PRM reflexes in essentially all lower limb muscles simultaneously. Transcutaneous spinal cord stimulation thus activates similar populations of sensory fibers as stimulation through epidural implants over the lumbar spinal cord (Fig. 5).

PRM reflexes have some electrophysiological similarities with the H-reflex (Minassian et al. 2011). They are enhanced by background voluntary activation of the target muscle and suppressed by contraction of the antagonist muscles or vibration applied on the tendons of the lower limbs. They are further characterized by excitability changes lasting up to 10 s following a prior stimulus. The simultaneous stimulation of multiple posterior roots results in transsynaptic effects other than (homonymous) monosynaptic excitation that may influence the PRM reflex of the target muscle, particularly when repetitively elicited in close succession (Minassian et al. 2011; Roy et al. 2012). Onset latencies of PRM reflexes to single pulses applied at incremental intensities to the lumbar spinal cord stay invariant and amount to 10.3 ± 1.1 ms for the quadriceps, 11.2 ± 0.4 ms for the hamstrings, 19.1 ± 0.9 ms for the tibialis anterior, and 19.7 ± 1.1 ms for the triceps surae (Minassian

Paraspinal Magnetic and Transcutaneous Electrical Stimulation, Fig. 5 Posterior root-muscle (PRM) reflexes evoked by transcutaneous and epidural spinal cord stimulation in the quadriceps (Q), hamstrings (Ham), tibialis anterior (TA), and triceps surae (TS) in a single incomplete spinal cord-injured individual. The

similarities of PRM reflexes elicited by either technique imply that transcutaneous stimulation depolarizes (a subset of) the same neural structures as activated by implanted epidural electrodes. (For details, see Ladenbauer et al. 2010; Minassian et al. 2011)

et al. 2007). Thresholds for eliciting PRM reflexes depend on the pulses applied (mono- or biphasic and their polarities), the individual physique, and the body position (e.g., supine or standing) and range from 20 to 40 V or 40 to 120 mA. The preferential activation of sensory roots minimizes an occlusion of the PRM reflex caused by antidromic volleys in the motor roots. Maximum PRM reflexes may attain amplitudes of up to 76% of the corresponding maximum M-wave (Kitano and Kocejka 2009) and depend on the excitability of the monosynaptic reflex in the target muscle (Roy et al. 2012).

Stimulation over the cauda equina (e.g., at L4-L5 vertebral levels) at incremental intensities results in a characteristic sequence of PRM reflex and M-wave elicitation, similar to the recruitment of sensory and motor fibers by stimulation of a mixed peripheral nerve (Minassian et al. 2007, 2011). Activation sites are at the intervertebral foramina, where posterior and anterior roots approach each other to form the spinal nerve. M-waves only are elicited in muscles innervated by the upper lumbar roots, e.g., quadriceps, that exit the spine rostral to such stimulation site. At threshold intensity, PRM reflex latencies are 13.3 ± 1.0 ms for the hamstrings, 21.1 ± 1.0 ms for the tibialis anterior, and 21.3 ± 1.1 ms for the triceps surae (Minassian et al. 2007). For

stimulation sites between the T11-T12 vertebrae and the distal cauda equina, M-wave and reflex contributions to the evoked composite CMAPs vary, depending on the position of the cathode along the lumbar spine (Roy et al. 2012).

Continuous transcutaneous stimulation (e.g., 30 Hz) over the T11-T12 vertebral levels produces paresthesias in the lower limb dermatomes (Hofstoetter et al. 2013b) that are normally associated with the stimulation of ascending sensory fiber branches within the posterior columns of the spinal cord white matter. The direct stimulation of the posterior columns is further suggested by the distribution of the paresthesias when graded stimulation is applied; with electrode placements evoking muscle responses in L2-L4 myotomes at threshold intensity, paresthesias are often produced in the L5-S2 dermatomes first. Yet computer simulations suggest that posterior column fibers have considerably higher thresholds than posterior root fibers; see Danner et al. (2011) and the entry ► “Finite Element Models of Transcutaneous Spinal Cord Stimulation.” Alternatively, the paresthesias can be explained by the stimulation of fibers from cutaneous receptors within the posterior roots as well.

Figure 6 summarizes the stimulated neural structures and their excitation sites for paraspinal magnetic and electrical stimulation.

Paraspinal Magnetic and Transcutaneous Electrical Stimulation, Fig. 6 Summary of neural structures directly stimulated by paraspinal magnetic (*MgStim*), high-voltage paraspinal electrical (*HVES*), and transcutaneous spinal cord stimulation (*tSCS*), respectively. Stimulation of (a) spinal root fibers and (b) long-tract fibers of the spinal cord white matter. Methods given in brackets indicate that stimulation is effective under specific conditions:

(1) reported in few muscles only, (2) only effective with specific magnetic coils and tissue current directions, (3) only with maximal stimulation intensities, and (4) not unequivocally demonstrated. *Open arrowheads* mark low-threshold sites of stimulation. (c) Drawing of the relevant anatomical structures; separation of the roots into several rootlets before entering the spinal cord is not illustrated

Applications

Lower Motoneuron Stimulation

Functional Assessment of the Cauda Equina and the Motor Root Conduction Time

One of the main clinical applications of paraspinal magnetic or high-voltage electrical stimulation is the neurodiagnostic assessment of the functional integrity of deeply located peripheral motor fibers. Within the cauda equina, the most proximal segments of the motor fibers can be affected by focal lesions caused by mechanical impacts to the spinal roots or root compressions. They are also involved in demyelinating peripheral neuropathies, with a degeneration of the myelin sheaths that slows down or completely blocks the conduction of action potentials. A method to assess the cauda equina is by the evaluation of the motor root conduction time (MRCT). The MRCT is calculated as the difference between the total peripheral motor conduction time (PMCT) and the latency of

the CMAP evoked by conventional paraspinal magnetic stimulation. The total PMCT is estimated by the F-wave method; for details, see Rossini et al. (1994) and Sandbrink (2008). The MRCT is the conduction time between the anterior horn cells and the actual site of activation of the motor fibers by paraspinal stimulation at the intervertebral foramen. Given a focal spinal root lesion, this neural excitation site would be distal to the affected segment of the motor fiber, and the latency of the CMAP would be normal, while the total PMCT would be delayed. The applicability of this method relies on the presence of F-waves and is therefore limited to a few distal muscles.

Alternatively, the lumbosacral MRCT can be estimated by paraspinal stimulation of the motor fibers at their two low-threshold sites, i.e., within the proximal and distal cauda equina, respectively. Large circular (Matsumoto et al. 2009b) and figure-8 (Maccabee et al. 1996) magnetic coils (both not commonly used in clinical practice), as well as high-voltage electrical stimulation

(de Noordhout et al. 1988), can activate the most proximal segments of the motor fibers at their origin from the spinal cord and their more distal portions at the cauda equina. The difference between the proximal and distal response latencies is the MRCT (or cauda equina conduction time, CECT; Maccabee et al. 2011). The CECT can be calculated for several roots simultaneously when recording CMAPs from multiple lower limb muscles. The total PMCT can be broken up into separate segments, including the cauda equina, upper leg, and lower leg conduction times (Maccabee et al. 2011). Axonal and (subtypes of) demyelinating neuropathies can be differentiated depending on the contributions of proximal or distal axon segments to the slowing of conduction. Axonal neuropathy involves degeneration of the entire axon rather than of the myelin sheath around the axon only, with the degeneration usually advancing from the axon's most distal portions toward the cell body.

The detection of cauda equina lesions and conduction blocks based on the measurement of the CMAP amplitude or area requires a technique providing for supramaximal stimulation, a criterion not fulfilled by conventional magnetic stimulation. High-voltage paraspinal electrical stimulation ensures supramaximal activation and can activate motor fibers within the anterior rootlets at their origin from the spinal cord, allowing for the exploration of the complete proximal nerve tract. The discomfort induced by high-voltage electrical stimulation is described as acceptable to excessive.

The cervical spinal nerves in the vertebral canal are short, and their conduction times have limited relevance for clinical diagnostics. The cervical MRCT can be calculated based on F-wave latencies and the response to paraspinal stimulation over the respective intervertebral foramina. Magnetic stimulation over the cervical and thoracic spine may be useful in the study of other deeply located nerves, such as the phrenic nerve and thoracic spinal nerves for the evaluation of nerve conduction velocity of the respiratory muscles. For details, see Rossini et al. (1994), Di Lazzaro and Oliviero (2005), and Sandbrink (2008).

Central Motor Conduction Time

Paraspinal stimulation combined with transcranial stimulation is used to calculate the conduction time in the fastest propagating central motor axons (i.e., axons of the upper motoneurons of the corticospinal tracts). Motor-evoked potentials (MEPs) elicited by transcranial stimulation of the motor cortex and electromyographically recorded from the target muscles provide for a noninvasive assessment of neurological disorders with upper motoneuron involvement. In clinical routine, the most important MEP parameter is the central motor conduction time (CMCT). The CMCT is the central component of the total MEP latency, i.e., the time from the stimulation of the cortex to the transsynaptic activation of the spinal motoneurons. The CMCT is obtained by subtracting the PMCT from the total MEP latency. The PMCT is estimated either by F-wave measurements or by paraspinal stimulation of the motor roots. For routine applications of motor root stimulation, many laboratories use conventional paraspinal magnetic stimulation. Since this method activates the motor roots in the region of the intervertebral foramen, the $CMCT_{mgn}$ calculated includes the conduction time along the anterior root and is estimated as too long (by 0.5–1.4 ms for cervical root stimulation and 3.0–4.1 ms for lumbosacral root stimulation; Sandbrink 2008). MEPs and the measurement of the CMCT can document corticospinal-tract involvement in patients with clinically evident upper motoneuron lesions. Further, the method may detect subclinical lesions, i.e., changes of the conduction properties of the corticospinal tract prior to clear clinical signs. Prolongation of the CMCT occurs with demyelination of the corticospinal fibers that contribute to the MEP, as in multiple sclerosis or segmental demyelination due to mechanical compression of the spinal cord (spondylosis or disk herniation). When recording from multiple muscles associated with different spinal cord segmental levels, the method may help identify the (rostrocaudal) location of a spinal cord lesion as well as assess mixed conus-cauda injuries. For further information, see Di Lazzaro and Oliviero (2005) and Sandbrink (2008).

Intraoperative Neuromonitoring

Nerve root damage is a potential neurological complication in lumbosacral spine surgery. High-voltage electrical stimulation of the proximal cauda equina can be applied to survey nerve root function during such surgery and to prevent potential damage to the nervous system. The principle is to provide for early detection of a nerve injury in an acute yet reversible state, hence allowing for immediate corrective procedures during surgery. During brief suspensions of the surgical procedure, single pulses are applied to produce supramaximal stimulation of the lumbosacral motor roots above the level of the surgical procedure. CMAPs are recorded from several muscles bilaterally innervated by L2-S2 spinal roots. Potential mechanical stress on the roots is immediately detected as a transient reduction of the CMAP amplitude in the respective muscles, caused by a conduction failure in the manipulated root. The technique is described in anesthetized patients undergoing lumbosacral surgery in degenerative spinal diseases (Troni et al. 2013).

Functional Magnetic Stimulation (FMS)

FMS produces patterned muscle contractions for useful bodily functions in people with upper motoneuron dysfunction. To this end, FMS applies timed, short sequences of repetitive magnetic stimulation (e.g., bursts of 25-Hz stimulation for 2 s) to the respective lower motoneurons. When the spinal cord is damaged, muscles below the level of the injury become (partially) paralyzed. Such paralysis does not only impede the ability to move but normally also affect the respiratory muscles, the gastrointestinal tract, and the bladder. Major muscles of inspiration include the diaphragm (primarily innervated by the phrenic nerve formed from the cervical nerves C3-C5), the parasternal muscles, and the external intercostal muscles (T1-T6 spinal nerves). Major muscles of expiration include the abdominal muscles (T7-L1 spinal nerves) and the internal intercostal muscles. Thus, with levels of injury from T12 to more rostral vertebrae, there is a progressive loss of respiratory motor function, with impairment of expiration and cough, further impairment of inspiratory and expiratory

function, and weakened respiration to the point at which ventilation cannot be self-sustained. FMS can be applied over the appropriate vertebral levels and to the respective motor roots to generate inspired and expired pressures. FMS of the cervical and upper thoracic nerves produces inspired volume and pressure and may be useful for enhancing inspiratory function and muscle conditioning. Similarly, FMS of the lower thoracic nerves produces expired volume and pressure and can be effective for simulating or restoring cough. An important advantage of FMS is that expiratory muscle activation can be achieved noninvasively. For limitations of the technique, see DiMarco (2005). Additional clinical applications of FMS include the stimulation of the sacral nerves for enhancing micturition and defecation function in selected spinal cord-injured persons with neurogenic bladder and bowel. For details on FMS as a therapeutic tool, see Lin and Hsiao (2005).

Corticospinal-Tract Stimulation

Evaluation of Corticospinal-Tract Function

The clinical value of high-voltage paraspinal electrical stimulation of corticospinal axons as a neurodiagnostic method is unclear. In principle, transcranial magnetic stimulation over the motor cortex together with high-voltage paraspinal stimulation at different vertebral levels may help localize alterations of the conduction properties along the fastest descending corticospinal axons and define the level of a spinal cord lesion. However, the technique does not allow for supramaximal activation, and the exact site of stimulation of the corticospinal tract below the paraspinal electrodes is not clear. Furthermore, with low-thoracic and more caudal stimulation sites, antidromic volleys within the posterior columns may add to the evoked response (Zidar 2001).

Human Motor Control Studies

High-voltage paraspinal stimulation of corticospinal axons may provide a measure of motoneuronal excitability for studying motor control of the lower limbs. The evoked responses are modulated in amplitude by volitional motor tasks

(Martin et al. 2008). These modifications provide information on the synaptic inputs onto the target motoneuron pools at the level of the spinal cord. The role of the corticospinal pathway in human motor control is normally investigated by transcranial magnetic stimulation over the motor cortex to evoke MEPs. Modulations of transcranially evoked MEPs during motor tasks can result from excitability changes within the motor cortex as well as at spinal cord segmental levels. In combination with transcranial magnetic stimulation, paraspinal stimulation may help identify changes of excitability at the motor cortex by providing a control for changes occurring at the lumbosacral segmental level (Martin et al. 2008).

Posterior Root Stimulation

Human Motor Control Studies

The H-reflex is a major noninvasive tool in human motor control studies. Due to the monosynaptic connections of Ia muscle spindle afferents to motoneurons, the H-reflex can be used to investigate excitability changes of the motoneuron pool supplied by the stimulated nerve. Transcutaneous posterior root stimulation extends H-reflex studies of a single muscle to the simultaneous assessment of monosynaptic reflexes at multiple lumbosacral segmental levels. This is relevant because motor control is organized multisegmentally, involving many muscles with state- and dynamic phase-dependent changes of their functional roles. Furthermore, posterior root stimulation can elicit monosynaptic reflexes in muscles that cannot be investigated by conventional peripheral nerve stimulation. PRM reflex modifications by motor tasks and passive movements were described in supine and standing positions and during treadmill stepping in subjects with intact nervous system as well as spinal cord injury (Minassian et al. 2007; Hofstoetter et al. 2008; Dy et al. 2010). For further details, see Minassian et al. (2011) and Roy et al. (2012).

Neuromodulation Applications

Neuromodulation therapies aim at improving functions in people with neurological disorders by continuous electrical or neuropharmacological

stimulation of specific neural networks of the central nervous system. Electrical stimulation methods in movement disorders, such as deep brain stimulation or epidural spinal cord stimulation, utilize electrodes implanted close to the input structures to the target neural networks. For the enhancement of motor control of the lower limbs by epidural spinal cord stimulation, local locomotor networks within the lumbar spinal cord are the natural targets. These networks are involved in the control of muscle tone, can execute stereotyped lower limb movements, and may remain functional below a severe damage to the spinal cord. Epidural lumbar spinal cord stimulation can control spinal spasticity (Dimitrijevic et al. 1986; Pinter et al. 2000), generate sustained extension (Jilge et al. 2004) and automatic flexion-extension movements of paralyzed lower limbs (Dimitrijevic et al. 1998; Minassian et al. 2004), facilitate task-specific training in clinically motor complete Harkema et al. 2011 and incomplete (Herman et al. 2002) spinal cord-injured individuals, and enhance endurance in people with residual walking capabilities (Huang et al. 2006). In many applications, the effects temporarily persist after the stimulation has been interrupted. For a review, see Minassian et al. (2012). Epidural lumbar spinal cord stimulation does not activate the locomotor networks directly but transsynaptically through large-diameter sensory fibers, predominantly within the posterior roots.

The consistent stimulation of these input structures also by transcutaneous spinal cord stimulation allows for its application as a neuromodulation method. When continuously applied, e.g., at a frequency of 30 Hz or 50 Hz, a “tonic drive” can be provided to the spinal cord below a lesion. Therapeutic applications of such tonic transcutaneous stimulation to alleviate spinal spasticity and enhance neural control of locomotion after spinal cord injury are being investigated (Minassian et al. 2011, 2012; Hofstoetter et al. 2013a, b). For the temporary modification of lower limb spasticity, 50-Hz stimulation is applied for 30 min in a supine position. The intensity is below the threshold for PRM reflexes but produces paresthesias in the lower limbs in individuals with remaining sensory

functions. Various manifestations of lower limb spasticity, such as clonus, spasms, and increased muscle tone, are modified after stimulation without loss of residual voluntary control (Hofstoetter et al. 2013b). During assisted, body-weight-supported treadmill stepping, continuous stimulation (e.g., 30 Hz) above the threshold for PRM reflexes has several effects in motor complete spinal cord-injured individuals, including suppression of clonus-like activities, augmentation of EMG activities of the paralyzed lower limb muscles generated by passive treadmill stepping, and generation of stereotyped, rhythmic EMG patterns not linked to the externally imposed gait cycle (Minassian et al. 2012). In motor incomplete spinal cord-injured persons performing active treadmill stepping, tonic transcutaneous stimulation at a sub-motor threshold level, producing paresthesias in the lower limb dermatomes, can immediately modify the voluntarily generated lower limb activities in a gait-phase appropriate way (Fig. 7). Augmented yet consciously controlled muscle activity may also lead to changes of the step kinematics, mainly to increase

maximum hip flexion angles and changes in stride length (Hofstoetter et al. 2013a). Further, 15-Hz stimulation can generate bilateral lower limb extension appropriate to produce a standing-up movement in spinal cord-injured people. As an assessment method, tonic transcutaneous posterior root stimulation may provide information on the altered physiology of spinal cord neural networks and can be complementary to the assessment via fast- and slow-conducting descending pathways.

Further Applications

Applications of paraspinal stimulation were described with evident neuromodulative effects but with the directly activated neural structures and the resulting physiological effects remaining speculative. Repetitive magnetic stimulation over the thoracic and lumbar spine reduces motoneuron excitability and spastic muscle tone in patients with spinal lesions (Nielsen and Sinkjaer 1997; Krause et al. 2004). Anodal direct current

Paraspinal Magnetic and Transcutaneous Electrical Stimulation, Fig. 7 Volitional treadmill stepping at 2 km/h of an incomplete spinal cord-injured person without and during the application of 30-Hz transcutaneous lumbar spinal cord stimulation. Electromyographic activities of the right quadriceps (*Q*), hamstrings (*Ham*), tibialis anterior (*TA*), and triceps surae (*TS*) along with goniometer

recordings of hip and knee angles and stance-phase markers. No manual assistance and body weight support provided. Stimulation was applied over the T11-T12 spinous processes at 27 V, an intensity generating paresthesias in the lower limb dermatomes without eliciting PRM reflexes

stimulation over the thoracic spine at 2–2.5 mA for 15–20 min modulates the excitability of central pain pathways in individuals with intact nervous system (Cogiamanian et al. 2011) and modifies spinal reflex activities in motor complete spinal cord-injured people (Hubli et al. 2013).

Definition

Chronic electrical stimulation also called deep brain stimulation (DBS) of specific nuclei in the basal ganglia is currently used to treat patients with movement disorders related to Parkinson's disease (PD). This entry reviews the clinical uses of, and mechanisms of, DBS to treat symptoms developed by patients with PD. The hope is that computational studies will lead to the development of better stimulation protocols which have better efficacy and involve DBS closed-loop stimulators external batteries.

Detailed Description

Parkinson's Disease

Parkinson's disease (PD) is the most common neurodegenerative disease. The median age-standardized annual incidence rates within high-income countries of PD is 14 per 100,000 people in the total population and 160 per 100,000 people aged 65 years or older (Hirtz et al. 2007). Males than females after the age of 60 years have a higher incidence (Taylor et al. 2007). The prevalence rates have shown steady age-related increase, shifting from 41 per 100,000 in the 40–49 age group to 1903 per 100,000 in people

older than age 80 (Pringsheim et al. 2014). PD incidence and prevalence are expected to grow over the next decades because of increasing efforts at extending the life span. Among the chronic disorders, PD is also considered one of the most difficult and challenging syndromes, and it substantially increases caregiver burden (Hassan et al. 2012).

This condition produces a wide variety of axial and distal manifestations that develop progressively. By the time the manifestations are noticed, around 70–80% of the pigmented dopaminergic neurons of the substantia nigra pars compacta located in the midbrain have already degenerated. As will be discussed below, the exact origin of the disease is still unknown. There is no known cure for PD.

Motor manifestations begin very gradually and include voice changes, tremor of extremities (unilaterally and then bilaterally which usually decreases during voluntary movement), tremor of the face, abnormal posture/gait (stooped posture, shuffling gait, falls, and freezing of gait), stiffness/rigidity/difficulty moving (with less amplitude of movement), bradykinesia, muscular weakness, and poor balance and coordination in most patients. Other motor features may include micrographia, a masklike face expression, and reduced eye blinks. Initially these manifestations usually affect one side of the body more than the other. Not all motor manifestations are present in a specific patient. Non-motor manifestations affect domains such as psychiatric/cognitive (anxiety, depression, fatigue, hallucination, impaired memory/concentration, sleep disturbance, etc.) but also autonomic (drenching sweats, dyspnea, orthostatic hypotension, sexual dysfunction, seborrhea, constipation, bladder symptoms) and sensory/pain (sensory disturbance, olfactory deficit) in most patients.

Parkinson's disease dementia (PDD) is one of the non-motor complications of Parkinson's disease that can occur in approximately 10% of PD patients (Emre et al. 2007). The symptoms are widely variable, but generally it is characterized by impairment of visuospatial and executive functions. PDD is often complicated by many neuropsychiatric symptoms such as mood disturbances,

apathy, and psychosis (Garcia-Ptacek and Kramberger 2016).

Dementia occurs with PD progression and there are currently limited treatment options (Deeb et al. 2018).

The prevalence of dementia in PD ranges from 20% to 40%. The PD phenotype presents pronounced variations across patients (Litvak et al. 2011).

The large spectrum of motor and non-motor manifestations listed above reflects multiple abnormal rhythms occurring in a large brain network of inhibitory and excitatory connections affected by the disease and involving the basal ganglia, thalamus, and cortex. Indeed, excessive synchronous activity throughout a corticobasal ganglia-thalamocortical network regulating the flow of information between the cortex and the spinal cord appears to be the hallmark of PD (McIntyre et al. 2004; Fig. 1). Furthermore, PD is not limited to the degeneration of the nigrostriatal dopamine system but is a widespread process involving multiple brain systems and neurotransmitters such as noradrenaline, serotonin, and acetylcholine.

Detailed Description of Parkinson's Syndrome

James Parkinson, a family physician in London, first described a “shaking palsy” or “paralysis agitans” in 1817 (Parkinson, see republication in 2002). During the nineteenth century, the disease was renamed Parkinson's disease by Charcot. In 1912, the presence of intracellular inclusion of Lewy bodies in brain cells of patients during postmortem examination was associated with PD. In 1917, the key role of a nucleus of the basal ganglia, i.e., the substantia nigra (pars compacta) in PD, was first described. Around 1959, the link between the presence of PD and the depletion of dopamine produced by neurons of the substantia nigra was established. Dopamine was shown to attenuate temporarily the symptoms in the 1960s. In the 1970s, the limitations of dopaminergic therapy used continuously over 5 years or more as a treatment of PD were discovered when side effects of the medication, e.g., severe motor fluctuations and on/off and wearing-off effects, became progressively as

Parkinson's Disease: Deep Brain Stimulation, Fig. 1 Highly simplified schematic view of the network circuitry affected by Parkinson's disease (McIntyre 2004) and illustrating the direct, indirect, and hyperdirect pathways

severe as or more severe than the symptoms caused by PD itself.

The physiological basis for PD remains unclear, and the process of neuronal death is still being actively explored. Several mechanisms have been proposed including mitochondrial dysfunction, protein mishandling, inflammation, oxidative stress, genetic and environmental factors, and aging (Pissadaki and Bolam 2013). But why would neuronal death affect specifically the substantia nigra pars compacta in PD? The explanation provided by Pissadaki and Bolam via computational modeling is that dopaminergic neurons are unmyelinated and each axon gives rise to more than one million synapses. This produces a high energy demand to propagate action potentials and renders these neurons highly vulnerable to any stressor perturbing energy production. It may eventually lead to cell death.

This cell death process probably involves multiple interacting causes such as genes, chemical agents, infective agents, and trauma. The syndrome is also associated with rare mutations in two genes encoding for alpha-synuclein and parkin which are somehow related to damaged proteins accumulating in neurons over time and leading to progressive cell death (Samii et al. 2004). The interaction between genes (up to 18 discovered so far) may confer increased susceptibility to PD which then appears usually before 50 years of age. These genes probably contribute to susceptibility to PD. Lewy body inclusion, as the hallmark of idiopathic PD

causing the death of nerve cells as previously believed, is questioned because these vesicles storing abnormal protein clumps of alpha-synuclein are found in PD (but not in all patients) as well as in other degenerative disorders such as Alzheimer's disease or even in persons with no neurological disease or no deficit in dopamine-producing nerve cells (Calne 2002).

Alpha-synuclein is coded by the gene SNCA. It accumulates initially in the olfactory system and lower brainstem and then travels in an anatomic pattern to involve other regions of the brain (Fahn 2018).

According to Calne (2002), the interplay of multiple genes with a specific but unknown environmental event causes the neurons to degenerate and die years later. This may explain why different forms of the disease exist. PD may take forms that vary from one patient to the other, and PD must also be distinguished from other similar conditions such as progressive supranuclear palsy and multiple system atrophy. This is why the diagnosis of PD often takes more than 1 year to be established in a relatively reliable way. Environmental factors hypothesized to play a role in inducing PD include exposure to pesticide, herbicide, and prolonged exposure to naturally occurring toxins. Some form(s) of influenza may also be associated with PD as the substantia nigra was shown to be vulnerable to viruses (Ogata et al. 1997). Recent evidence according to Calne (2002) also suggests that a brief event (e.g., injury from a toxin or a virus wounding nerve cells) may kill

some cells immediately and damage many others in ways that decrease their life expectancy. Recent and growing evidence on the bidirectional interactions between the gut microbiota and the central nervous system suggests that several health conditions including Parkinson's disease may be affected by intestinal microbiota (the "enteric" brain).

Pathophysiology of PD

As indicated before, the primary deficit in PD is the loss of neurons in the substantia nigra pars compacta. These neurons provide dopaminergic innervations to the striatum (caudate and putamen). Dopamine, a catecholamine synthesized by neuron terminals from metabolized tyrosine by tyrosine hydroxylase (to L -DOPA) and by dopa decarboxylase from L -DOPA to dopamine, can temporarily restore function. The action of dopamine is mediated by a family of dopamine receptor proteins (D1–D5) which can be divided into two groups having different structural and pharmacological properties (D1 and D5 on one side and D2, D3, and D4 on the other); however, D1 (excitatory) and D2 (inhibitory) appear to be the most important receptor sites with regard to PD. The exact effects of DBS on neurotransmitters are still being explored today (but see Shon et al. 2010).

Considerable effort has been devoted to exploring the link between dopamine loss and the spectrum of clinical features observed in PD (Albin et al. 1989; Alexander et al. 1990). As indicated already, the basal ganglia are part of the complex network including not only the cortex and the thalamus but also other structures such as the brainstem and cerebellum. This large network regulates the flow of information going to and from the cortex. The striatum is the principal input structure of the basal ganglia, and it receives excitatory glutamatergic input from a large region of the cortex (Fig. 1). The outflow of the striatum is divided into the direct pathway expressing primarily D1 excitatory receptors and the indirect pathway expressing primarily inhibitory D2 receptors. Dopamine appears to increase the activity of the direct pathway and reduce the activity of the indirect

pathway, while PD produces the opposite effect. This imbalance is believed to explain the symptoms of the disease (Fig. 1). But what is the nature of pathological activity in the basal ganglia-cortex network? There is a first frequency band around 20 Hz closely related to bradykinesia and rigidity (but not directly related to muscle activity for bradykinesia) and a second frequency band around 10 Hz related to tremor and correlated with muscle activity. Litvak et al. (2011) examined the interconnectivity between brain areas and distinguished a network around 10 Hz in the temporoparietal-brainstem areas and another predominantly frontal network around 20 Hz.

Today, no treatment can stop the progression of the disease. But symptoms can be attenuated by pharmacologic intervention (L -DOPA, dopa agonists, etc.), ablative surgery, surgery for neuromodulation (DBS), and gene therapy. Pharmacologically during the early phase of the disease, the patient is treated with dopamine and dopamine agonists (acting on dopamine receptors) (Jankovic and Aguilar 2008). The treatment is given in the form of L -DOPA, which passes through the blood-brain barrier and is converted into dopamine. During the later phase of the disease inhibitors such as MAO-B (monoamine oxidase B), an enzyme metabolizing dopamine which delays or reduces the breakdown of dopamine, and COMP (catechol O-methyl transferase), which increase the half-life of L -DOPA, may be added. Anticholinergics are also used to improve symptoms such as tremor. Levodopa-induced motor complications appear after a few years of treatment and produce fluctuations in motor response and involuntary movements (dyskinesias). These complications may include strong wearing-off effects or freezing during long "off" periods between doses.

Deep Brain Stimulation

Deep brain stimulation (DBS) for PD involves continuous therapeutic electric stimulation of subcortical structures at frequencies >100 Hz using chronically implanted electrodes. It is a highly effective and reversible surgical procedure,

**Parkinson's Disease:
Deep Brain Stimulation,**
Fig. 2 DBS from McIntyre
(2004)

meaning that it has marked benefits and morbidity limited to around 0.2% (Fig. 2). Its origin goes back to work done on epileptic patients (Krause 1912), and its success is largely based on past long-term experience with surgical ablation of deep brain structures such as the ventrointermediate nucleus of the thalamus (Vim) which was replaced by Vim stimulation by Benabid et al. (1987).

A surgically implanted battery-operated pulse generator (IPG) delivers high-frequency electrical stimulation to targeted deep areas of the brain via one (unilateral) or two (bilateral) implanted platinum iridium electrodes (or leads) connected to the generator via an extension. The IPG or neurostimulator is subcutaneously implanted in the pectoral or abdominal region (Fig. 2). The insulated polyurethane extension is passed subcutaneously from the chest, the side of the neck, to the top of the cranium and connected to an electrode which is lowered slowly to a predetermined target. The system is subsequently programmed using radio signals.

The most common targets in PD today are the subthalamic nucleus (STN) and the globus pallidus internal segment (GPi), mainly proposed for the treatment of motor symptoms (Anand Rughani et al. 2018).

Increasing evidence from randomized clinical trials indicates that motor benefit is similar between both targets, including improvement in quality of life.

DBS of the STN reduces dopaminergic medication and offers possible mild benefit in non-motor domains and potential economic advantage (Ramirez-Zamora and Ostrem 2018).

Motor scores assessed in the “off” medication/“on” stimulation condition improve much more with STN stimulation (Rughani et al. 2018).

GPi DBS shows more likely a suppression of dyskinesia and an improvement in depression (Rughani et al. 2018). Overall, STN DBS has a higher risk for behavioral changes compared with GPi DBS. For these reason, target selection should be customized to each patient’s clinical manifestation and neuropsychiatric profile, allowing personalization of this therapy and improved individual outcomes (Ramirez-Zamora and Ostrem 2018).

Stimulation parameters (stimulus polarity, pulse amplitude, pulse duration, and stimulus frequency) are empirically adjusted by the clinician to minimize side effects while optimizing symptom reduction. DBS induces an electrical field in the tissue surrounding the contact. This electric field is strongest at the cathode and decays with distance.

DBS in PD reduces on average by 50% the motor scores of the UPDRS (Unified Parkinson's Disease Rating Scale) and the daily dose of L -DOPA, while patients' quality of life significantly increases. The effect of DBS is observed within seconds. The efficacy of DBS is now widely recognized, and over 80,000 patients worldwide benefit from this surgical intervention. This treatment option has been tried in a variety of disabling pathological conditions refractory to medications and other than PD including dystonia, essential tremor, chronic pain, obsessive compulsive disorders, Tourette's syndrome, and depression. These applications require different stimulation sites along the corticobasal ganglia-thalamocortical network (Fig. 1). Although DBS is the procedure of choice today, it is invasive and expensive and involves surgical risks (hemorrhage 1–2%, infection 3–5%) as well as hardware complications such as leads breaking, electrode malfunction, and battery failure. Furthermore, side effects (such as postural instability, depression, speech difficulties, gain of weight, decline in cognitive-motor functioning) are not uncommon.

There are still limitations in terms of effectiveness, side effects, and battery consumption. For these reasons only pathological neural activity can be suppressed while stimulating: adaptive DBS (aDBS), where stimulation is applied according to the level of pathological activity, might be advantageous (Beudel and Brown 2016).

Detailed Description of Deep Brain Stimulation

Electrical motor cortex stimulation goes back to the work of Aldini (1803) who applied noninvasive therapeutic cortical stimulation in a psychiatric patient for the first time. Extirpation of premotor and cortical motor zones was used to control movement disorders by Horsley (1890), Bucy and Buchanan (1932), Bucy and Case (1939), and Klemme (1940, 1942) often with limited success. Alberts (1972) showed that stimulation of the motor cortex at 60 Hz near the Rolandic fissure between motor and sensory sites evoked or augmented a 5 Hz tremor in PD patients, while Woolsey et al. (1979) observed that stimulating currents subthreshold for the elicitation of

movement resulted in disappearance of tremor and rigidity for short periods after stimulation of the primary motor cortex in a patient with severe PD.

Surgical interventions have been described since the 1940s and have consisted in lesioning various structures. The most common lesioned structures were the thalamus and the pallidum. The destruction of these targeted areas was successful in controlling the symptoms of PD, but the procedure was irreversible. After the discovery of the side effects of L -DOPA, surgical treatments were reintroduced in the 1980s. At that point, one nucleus of the thalamus (i.e., the Vim) was not irreversibly destroyed, as previously done, but chronically electrically stimulated. Other structures (GPi, STN, zona incerta) were shown to produce positive effects on the symptoms although these effects were slightly different.

DBS Indications and Benefits

DBS is used for patients with onset of PD of at least 4 years duration associated with 4 months of motor complications. It can improve tremor, rigidity, slowness of movements, and drug-induced dyskinesias (Pollo et al. 2014).

Patient inclusion criteria also contemplate dopamine-responsiveness and absence of significant cognitive dysfunctions and emotional stability with no severe psychiatric symptoms. Both sporadic and genetic PD patients are eligible for DBS (Moro and Lang 2006).

The benefits of DBS include attenuation of drug-induced dyskinesias and improvement in quality of life (Ruth-Mary de Souza et al. 2013).

Benefits of neuromodulation can be maintained for more than 10 years, but the effect of DBS might be maintained in all motor domains except axial symptoms (Hariz 2017).

The motor function attenuation consists in significant improvement in tremor and bradykinesia, but not in axial motor function. Improvement of non-motor features are pain, akathisia, cognitive function, emotion, activities of daily living (ADL) scores, autonomic function, and aspects of life such as employment, family roles, and social interaction.

DBS may have benefit in early PD when fewer neurons have been lost, reducing brain damage. STN DBS raises striatal dopamine levels and also increases levels after L-DOPA administration in patients experiencing the wearing-off phenomenon. It is also true that patients who had STN DBS in situ for 8–10 years had maintenance of motor benefits and functional improvement despite reduction in L-DOPA dose but had significant decline in postural stability, axial symptoms, and a nonsignificant decline in cognition (de Souza et al. 2013). STN DBS is effective in ameliorating PD symptoms; furthermore it is the only surgical procedure for PD that allows a radical decrease in medication (Hariz 2017).

DBS may modulate also non-dopaminergic networks, which may in the long term impact non-motor clinical features of PD (de Souza et al. 2013).

DBS also allows modification of the stimulation delivered to the precise brain targets: it allows to obtain maximal benefit with minimal side effects.

The individual clinical benefit of directional DBS is best observed for suboptimal electrode positions resulting in a narrow therapeutic window (Steigerwald et al. 2016).

DBS Disadvantages

The main disadvantages of DBS are the cost (approximately \$10,000 per unit), the increased risk of infection, the cost of maintenance, and battery exhaustion (Konstantin et al. 2017).

Stimulation may be limited by the apparition of acute disabling side effects such as tonic muscular contractions, dysarthria, conjugate eye deviation, paresthesia, or gait imbalance: the electrode size has an important influence on the occurrence of side effects (Pollo et al. 2014).

DBS Targets

The main targets for DBS are STN, GPi, Vim, pedunclopontine nucleus, caudal zona incerta, substantia nigra pars reticulata, and motor cortex.

The target is different in order to the symptom control.

GPi DBS causes less cognitive decline than STN DBS and can be taken into account in PD

patients with preoperative cognitive impairment: however STN and GPi are the main targets of DBS to alleviate motor symptoms.

Vim helps primarily with tremors.

Alternative DBS targets are pedunclopontine nucleus, caudal zona incerta, substantia nigra pars reticulata, and motor cortex. They are important for control of speech, swallowing, and non-motor symptoms such as memory impairment, attention decline, and sleep disturbances. (Mehanna et al. 2018).

Another target is the nucleus basalis of Meynert (NBM): it is the most important source of cholinergic innervations to the neocortex. The DBS of the NBM is a therapy for PDD.

The purpose is to provide insights into the cholinergic network underpinning cognitive dysfunction (Deeb et al. 2018).

DBS Innovations

The most recent advantages in the DBS field include interleaving of DBS pulses, fractionated current, directional steering of current, use of biphasic DBS pulses, and closed-loop stimulation. The next frontiers should be the remote internet-based programming.

DBS should improve mortality and it could have neuroprotective effects (Mehanna et al. 2018).

DBS Outcomes

Age at surgery and duration of the disease do not seem to influence the outcome. Postural instability and worse pre-DBS motor score are the strongest predictors of poorer functional and QOL outcomes. Furthermore there is a possibility of significant weight increase after DBS in advanced PD: it is a problem especially in case of obesity, diabetes, and other metabolic disorders (Mehanna et al. 2018).

DBS Mechanisms

The mechanisms of action underlying the beneficial effects of DBS are still actively debated, and progress has been relatively slow at first despite a large catalogue of hypotheses proposed about DBS underlying physiological mechanisms (for some examples, see Montgomery and Gale 2008; Johnson et al. 2008; Vitek 2008; Modolo

and Beuter 2009a, b; McIntyre and Hahn 2010; Miocinovic et al. 2013; Rubin et al. 2012). DBS was initially thought to suppress pathological rhythms (Vitek 2002; McIntyre et al. 2004; Hammond et al. 2008).

The electrical stimulation induced an inhibition of basal ganglia output structures, decreasing basic firing of neurons and suppressing spontaneous neuronal activity. The possibility of depolarization blockade may occur through K⁺-mediated effects, Na⁺ channel inactivation, presynaptic depression of excitatory efferents, and hyperpolarization of neuronal bodies and dendrites. DBS causes glutamate reduction and increases of inhibitory neurotransmitters such as GABA.

Neurovascular and neurogenic changes may be induced by electrical stimulation of the brain: in fact DBS induces an increase in blood flow and neurochemical changes that may be induced by stimulation of astrocytes and propagation of calcium waves resulting in release of glutamate (Martinez-Ramirez et al. 2015).

The comparable outcome after a lesion and during stimulation of a cerebral structure has led to the conclusion that DBS inhibited neuronal activity and decreased output from the stimulated structure, and this hypothesis was supported by a number of studies performed in humans and animals (see, e.g., Dostrovsky and Lozano 2002; Perlmutter et al. 2002). Other potential mechanisms invoked include a depolarization blocking of neuronal transmission through inactivation of voltage-dependent ion channels (Benazzouz et al. 1996; Beurrier et al. 2001; Bikson et al. 2001) and synaptic inhibition by stimulation of inhibitory afferents to the target nucleus (Dostrovsky et al. 2000; Breit et al. 2004) and synaptic depression by stimulation-induced neurotransmitters depletion (Urbano et al. 2002; Xia et al. 2004). DBS mechanisms were also described as creating a jamming of information by imposing an afferent stimulation-driven high-frequency pattern (Garcia et al. 2003; Hashimoto et al. 2003; Breit et al. 2004) or as “an informational lesion” (Grill et al. 2004) preventing pathological activity from spreading through the basal ganglia.

As pointed out by Montgomery (2012), the effects of DBS are not only local but also

system-wide. Indeed, for Lozano et al. (2002), stimulation of deep brain structures could potentially “backfire” to the thalamus and cortex. Studies proposed that DBS inhibited somatic activity at the site of stimulation (close to the electrode, mimicking the outcome of a lesion) and excited axons (output of the stimulated area). In other words, in a cell exposed to extracellular stimulation, the stimulus-induced action potential initiates in the axon rather than in the cell body and axonal spike output becomes time locked to the stimulus frequency as shown in a modeling study by McIntyre et al. (2004). In addition, fiber tracts of passage are activated. For example, the STN is surrounded by several major fiber tracks (lenticular fasciculus, field of Forel, zona incerta, cerebellothalamic fibers, etc.) as well as fibers coursing through the target nucleus (Johnson et al. 2008; Hammond et al. 2008). This paradox between inhibition of the stimulated structure and simultaneous activation of downstream structures was later shown to be related to the distance from the electrode. This explanation, however, does not entirely explain why therapeutic latencies differ between symptoms (Johnson et al. 2008). Another conclusion was that pathological synchronism in the STN is present in PD and this, rather than firing rate, is the pathological feature in PD. DBS changes the firing pattern of STN neurons (Carlson et al. 2010; Wilson et al. 2011).

Several studies focused more specifically on network activity (McIntyre and Hahn 2010; Asanuma et al. 2006) including short- and long-term effects, as well as local and distant effects of DBS (for examples, see Titcombe et al. 2001; Montgomery Jr and Gale 2008; Brown and Eusebio 2008; Santaniello et al. 2012). In the corticobasal ganglia-thalamocortical network, the best site of electrode implantation could be located theoretically at any point of the network (Fig. 1). This is confirmed by the fact that improvements have been reported when various structures along this network are stimulated. Combining modeling with experimental and clinical components brought new insights. Thus, neurostimulation therapy modulates activity in the corticobasal ganglia network. This modulation has been described as stimulation-induced

desynchronization of network oscillations (McIntyre and Thakor 2002). Thus, not only does DBS appear to override the irregular, pathological activity of the stimulated target with a regular pattern, but the effect produced spreads through then tire network (Xu et al. 2008; Johnson et al. 2008; McConnell et al. 2012; Miocinovic et al. 2013).

In brief, DBS effects are likely to result from a combination of local changes and modulation of distant structures within the corticobasal ganglia-thalamic loops. The involved mechanisms include the activation of afferent and efferent axons, with both antidromic and orthodromic spike propagation (Hanajima et al. 2004; Deniau et al. 2010; Santaniello et al. 2012). Studies are converging on the fact that excessive synchrony propagating and amplifying around this network can be explained by a resonance phenomenon (i.e., a sensitivity of neurons to afferences having frequencies close to their intrinsic frequency) and high-frequency DBS appears to attenuate subthalamic as well as cortical rhythms in PD.

As indicated above, pathological discharge patterns generated in the basal ganglia in PD propagate around the network, and DBS probably modulates brain rhythms, especially abnormal synchronous oscillatory activity in the beta band (Brown 2003, 2006; Wingeier et al. 2006) but also theta and alpha rhythms (Whitmer et al. 2012) in the STN and cortex (primary motor cortex, premotor cortex, somatosensory cortex, and orbitofrontal cortex) (Walker et al. 2009). This rhythmic activity manifests itself as oscillatory local field potentials (LFPs, i.e., extracellular voltage fluctuations in membrane potential of a local neuronal population), which are recorded with macroelectrodes at various sites within the network. Thus, part of the explanation of DBS effects is local suppression of pathological oscillations (i.e., excessive synchronous) in specific frequency bands throughout the corticobasal ganglia-thalamocortical network (Eusebio et al. 2012; Whitmer et al. 2012).

Two remarks to keep in mind. The first one raised by Johnson et al. (2008) is that methodological approaches vary greatly among studies and complicate the exploration of mechanisms,

and the second is that few attempts to model DBS effects were reported during the initial years (but see Tass 1999, 2000; Titcombe et al. 2001, Rubin and Terman 2004). DBS appears to cause a cascade of effects probably involving a combination of mechanisms; some of these mechanisms are still unknown (e.g., is there a gliomodulation in addition to a neuromodulation?). These mechanisms are currently being explored using imaging, electrophysiology, and model-based network level analysis incorporating network dynamics in response to stimulation (McIntyre and Hahn 2010; Liu et al. 2011).

DBS Surgical Procedure

For targeting and planning the implantation trajectories, preoperative T1 and T2 weighted high-resolution magnetic resonance images (3 T) are used, and they are co-registered with a stereotactic CT scan (Pollo et al. 2014).

The anterior commissure/posterior commissure (AC-PC) line is a helpful to determine the orientation of each lead within stereotactic space and assigned each directional setting to an orientation (Steigerwald et al. 2016).

The electrode is inserted under fluoroscopic control, and impedance through each contact is also measured as a confirmation that the stimulation takes place as intended (Pollo et al. 2014).

DBS Electrodes

The Vercise DBS device (Boston Scientific Corporation, Natick, Massachusetts, USA) is capable of delivering multiple source constant current allowing the allocation of completely different stimulation parameters independently to each of eight contacts of the electrodes. It allows the clinician to shape the current along the vertical axis of the electrode (Barbe et al. 2014). It is associated with a pulse generator capable of multiple independent current source control (MICC). MICC allows to distribute the stimulation current over any combination of electrodes of one lead in arbitrary proportions (Steigerwald et al. 2016).

The Infinity DBS device (St. Jude Medical – Abbott) consists of a directional, segmented lead that offers new ways to control stimulation and an IPG that is the first and only one compatible

with other manufacturers' existing extensions without use of adapters. With this technology, we can customize the therapy by targeting specific anatomical structures, steer current away from vulnerable structures, and support lead capture through secure lead fixation using the Guardian™ Burr Hole Cover auto-locking technology.

A further prospect is to shape or steer the current delivered according to all three axes.

Both electrode designs consistently showed a significant widening of the therapeutic window with stimulation in the best direction compared to the conventional spherical stimulation (Pollo et al. 2014); Dembek et al. 2017).

There was no difference in motor efficacy or stimulation amplitudes between directional and circular DBS in the short-term crossover. A relevant expansion of the therapeutic window is demonstrated with directional stimulation (Dembek et al. 2017).

Chronic implantation is now needed to establish the usefulness of directional steering in the long term (Mahlknecht et al. 2015). The observed side effects related to direction of stimulation were consistent with the anatomical location of the surrounding structures (Pollo et al. 2014).

Particle-Based Stochastic Simulators

Steven S. Andrews

Division of Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, USA
Department of Physics, Seattle University, Seattle, WA, USA

Definition

A stochastic simulator that tracks the location and interactions of individual molecules of interest. Molecules are represented with minimal internal detail.

Detailed Description

Computational simulations are widely used in neuroscience, as in other branches of biology, to explore the implications of quantitative models. They are used to investigate the sequestration of calcium calmodulin kinase II (CamKII) in dendritic spines, the transmission of action potentials through networks of neurons, and the release of heterogeneous synaptic vesicles, among many other topics. Some simulations are used with abstract “toy models” to identify fundamental

biological principles, such as which signaling network topologies can transmit information particularly accurately. Others are tightly integrated with experimental work to build better understandings of particular systems.

Neuroscience simulation methods can be broadly categorized by the level of detail that they represent. At the coarse end of the scale, one can numerically integrate the differential rate equations that represent the kinetics of biochemical reaction and transport processes (Aldridge et al. 2006). Such integration methods typically assume few spatial compartments and ignore stochasticity. At the other extreme lie molecular dynamics approaches, in which one simulates the intricate motions of individual atoms within potential energy landscapes (Rapaport 2004). In moving along the continuum from coarser to finer levels of detail, these simulation methods typically address smaller total volumes of space, simulate shorter amounts of time, require more simulation parameters, and become more computationally intensive. They also consider space more realistically, such as by moving from a compartment description to a lattice, and then on to continuous space. In addition, the simulators change from using deterministic computations, which are appropriate when enough molecules are considered that their fluctuations become irrelevant, to stochastic computations, which account for natural fluctuations and are essential when there are few molecules.

Particle-based simulations lie toward the detailed end of this scale. They track the locations and interactions of all individual molecules of interest, while ignoring water and other molecules that are not of interest. They typically address sizes that range from single nanometers to tens of microns, and time scales from tens of nanoseconds to minutes. This level of detail makes them good for simulating problems involving molecular diffusion, chemical reactions, macromolecular complex formation, and/or molecule-membrane interactions. Their level of detail would also make them appropriate for investigating dynamics involving the conformations of cytoskeletal and nucleic acid filaments (Andrews 2014), although those topics have received less attention so far and

are minimally supported in current software. Particle-based methods lie between the coarser spatial Gillespie methods (e.g., Drawert et al. 2012) and the finer Brownian and molecular dynamics methods (Ermak and McCammon 1978; Rapaport 2004).

Naively, it might seem best to work at the highest possible level of detail because it is the most accurate. In fact though, the opposite is generally the case. It is typically best to work at the lowest level of detail that adequately addresses the research question at hand because doing so enables simpler models and faster simulations; the importance of faster simulations should not be underestimated because simulation speed largely dictates the pace of the research and determines the extent of parameter scanning and parameter fitting that are practical. Furthermore, there is little benefit in simulating a model with more detail than is in the model itself. For example, simulating encounters between structurally complicated proteins with subnanometer precision is not meaningful when those same proteins are being approximated as perfect isotropic spheres.

Many particle-based simulators have been developed over the past three decades (see reviews Blackwell 2013; Sokolowski and ten Wolde 2017; Schöneberg et al. 2014). Of these, we are aware of six that are being actively maintained, meaning in this case that they have had new releases in the past 3 years. These simulators are described below and in Table 1, listed roughly in order of increasing detail. The simulators that are not listed here (see Schöneberg et al. 2014) are generally less mature, with fewer features, less documentation, and/or more difficult installation.

MCell and Smoldyn

MCell (Stiles and Bartol 2001, <http://mcell.org>) and Smoldyn (Andrews et al. 2010, <http://www.smoldyn.org>) work at similar levels of detail. Both are able to represent molecules as point-like particles that diffuse freely and only interact when pairs of reactants collide with each other and then undergo a chemical reaction. These molecules can

also adsorb to surfaces, desorb from surfaces, and diffuse along surfaces. Both programs are mature, with easy installation, good documentation, and many features. MCell was initially developed for modeling reactions and diffusion in the neuromuscular junction (Stiles et al. 1996) and continues to be used for a wide variety of neuroscience simulations. MCell supports molecules with multiple states, such as arise with phosphorylation (Stefan et al. 2014). It has a graphical user interface that works with the open-source Blender software and provides excellent graphical output.

Smoldyn does not support graphical input but reads text input files instead. Smoldyn's graphical output, which displays as the simulation runs, is good but inferior to MCell's. On the other hand, Smoldyn runs about three times as fast as MCell, is more accurate (Andrews et al. 2010; Andrews 2017), and offers more features. All of Smoldyn's algorithms approach exactness, meaning perfect agreement with the underlying conceptual model, as time steps are reduced towards zero and it also simulates reaction rates, on-surface diffusion, and molecule-surface interactions quite accurately even with very long time steps. Smoldyn allows molecules to have excluded volumes, enabling simulations of macromolecular crowding. Smoldyn offers rule-based modeling, with either BioNetGen or a new wildcards method, for modeling the dynamics of multimeric complexes. It also offers multiscale simulation using spatial Gillespie approaches and has been combined with partial differential equation (PDE) methods in the popular Virtual Cell software (Schaff et al. 2016). Smoldyn is used particularly in the biophysics and systems biology communities.

E-Cell and eGFRD

The enhanced Green's Function Reaction Dynamics (eGFRD) algorithm (Takahashi et al. 2010) is an exact approach for simulating chemical reactions between molecules that can be represented as perfect spheres. Simulated molecules diffuse in agreement with ideal Brownian motion and

nonreactive pairs of molecules reflect off of each other upon collision to account for excluded volume effects. Bimolecular reactions exactly obey the Collins and Kimball chemical reaction model, in which molecules are treated as hard spheres that have an “intrinsic reaction rate” when in contact (Rice 1985); this model is widely assumed in the particle-based simulation field. The eGFRD algorithm achieves this high level of detail by using an event-driven method in which it steps the simulation time from the moment of one interaction event to the moment of the next event. The two original algorithm developers, Takahashi and ten Wolde, have now implemented it in separate software:

E-Cell (Tomita et al. 1999, <http://www.e-cell.org>), a platform that offers simulators that work at several levels of detail, and eGFRD (<http://gfrd.org>), which only runs the eGFRD algorithm.

The eGFRD algorithm is very efficient for dilute systems because it does not simulate multiple diffusive steps between molecule encounters. However, it is slow for dense systems because these have a large number of molecule encounters and the algorithm performs complicated calculations at each one. For example, I found that it was several orders of magnitude slower than Smoldyn when simulating a Michaelis-Menten reaction that started with 10,000 molecules (Table 1). This

result agreed with speed differences found when testing reaction accuracy (Table 1) and in a prior macromolecular crowding study (Andrews et al. 2015).

SpringSaLaD and ReaDDy

SpringSaLaD (Michalski and Loew 2016, <http://health.uconn.edu/cell-analysis-modeling/ccam-software/>) and ReaDDy (Schöneberg and Noé 2013, <http://www.readdy-project.org>) were designed to bridge the gap between simulation approaches that treat molecules as perfect spheres and molecular dynamics methods. These simulators represent individual molecules as collections of spheres that are bound together with either springs, in the case of SpringSaLaD, or with interaction potentials, in the case of ReaDDy. Both simulators move the separate spheres by numerically integrating the equations of overdamped Langevin dynamics, a physical theory that combines the fluctuating forces that drive Brownian motion and the viscous drag forces that slow it down. This integration requires very short time steps, typically on the order of 1–10 ns (although not its main purpose, ReaDDy can also ignore inter-particle potentials, resulting in much faster simulations). SpringSaLaD represents cell membranes and other surfaces minimally, using a single planar membrane within the simulation volume, while ReaDDy represents surfaces using a combination of planes or spheres, each of which can interact with molecules through an interaction potential.

SpringSaLaD and ReaDDy are particularly useful for simulating the dynamics of protein complexes, such as the multiple subunits of CamKII, along with their interactions with surrounding molecules. This greater level of detail makes these simulators more computationally intensive. They are generally best for systems with a thousand molecules or fewer and can simulate up to a few milliseconds of total time.

Conclusion

Particle-based stochastic simulators are powerful tools for exploring the roles of spatial organization and stochasticity in cell-scale systems. They are used widely in neuroscience research at present

and will undoubtedly be used more in the future as the software improves, computers run faster, and biology research becomes more quantitative. Current simulators are able to accurately represent the diffusion, chemical reactions, complexation, and membrane interactions of individual molecules of interest. These simulators work at different levels of detail, ranging from MCell, which treats molecules as point-like particles, to ReaDDy, which addresses interaction forces between portions of molecules.

All of the tools described here are open source and have nonrestrictive licenses that allow for both commercial and noncommercial use. They are also works in progress that are frequently expanded and improved in response to users' needs. Although perhaps less evident, each simulator is also the product of many person-years of development and testing. If you need a capability that is not supported by one of these tools, I encourage contacting the teams that work on these programs for advice on working around limitations before spending time writing new code.

Patch Clamp Technique

Thomas Nowotny¹ and Vincenzo Marra²

¹Centre for Computational Neuroscience and Robotics, School of Engineering and Informatics, University of Sussex, Falmer, Brighton, UK

²Department of Cell Physiology and Pharmacology, University of Leicester, Leicester, UK

Definition

The patch clamp technique is an electrophysiological technique used to measure the currents passing through ionic channels and the membrane potential of electrically active cells. This technique was first introduced by Neher and Sakmann (1976), and it is now widely used in neuroscience to characterize the electrical properties of neuronal membranes.

Detailed Description

Patch clamp recordings are obtained by electrically isolating a patch of membrane using an electrolyte-filled glass capillary in close proximity to the cell membrane. A silver or silver chloride electrode inserted at the other end of the capillary will provide electrical continuity with a reference electrode placed in the extracellular bath solution (Fig. 1). The lipid bilayer which constitutes the cell membrane will seal onto the glass capillary forming what is generally described as a gigaseal, to indicate that the resistance between the tip of the pipette and the reference electrode is on the order of gigaohms (Fig. 2a). To obtain the gigaseal, mild positive pressure is applied at the back of the pipette so that liquid escapes from the approaching tip and pushes the membrane inward before the electrode touches the cell. This will create a dimple on the surface of the cell. When the tip of the pipette is close enough to the dimple, the positive pressure is released and a very gentle suction is applied allowing the membrane to seal

Patch Clamp Technique,

Fig. 1 Patch clamp recording setup. The patch clamp electrode is placed on a cell membrane, and the recorded signal is preamplified in the headstage. Further amplification occurs at the amplifier. The signal is then digitized and recorded on a measurement computer

Patch Clamp Technique, Fig. 2 Illustration of patch clamp configurations. (a) Equivalent electrical circuit of a whole-cell patch clamp recording configuration. (b)

Schematic illustration of how the four main patch clamp recording configurations are achieved

onto the glass. At this point, a small negative current is often applied to improve the quality of the seal and maintain the patch of membrane slightly hyperpolarized.

Setup

Once the gigaseal is obtained, the electrical properties of the membrane can be measured. The minimal setup required for patch clamp recordings is relatively simple (see Fig. 1). The glass capillary is mounted on a headstage which

contains a current-to-voltage circuit for voltage clamp recordings or a voltage follower circuit for current clamp. The headstage is in turn mounted on the micromanipulator to allow precise positioning of the pipette (not shown). The signals are then sent to the amplifier which will compensate for recording artifacts, filter the signal, and amplify it. The signal from the amplifier is then digitized by an analog-digital converter and visualized and stored on a computer. Before the widespread use of personal computers, the recordings were visualized and stored using oscilloscopes and chart recorders.

Single-Channel Patch Clamp

Single-channel recordings can provide information on the ionic gating properties of ionic channels (opening/closing time, inactivation, conductance, etc.) as well as their pharmacology (affinity to neurotransmitters, agonist, antagonists, etc.).

The first application of the patch clamp technique was to record current passing through a single ionic channel, more precisely an ionotropic acetylcholine receptor (Neher and Sakmann 1976); however, the properties of voltage-gated ionic channels can also be studied by applying voltage steps through the amplifier (see ► [“Voltage Clamp Technique”](#)). The solution in the patch pipette is very similar to the extracellular solution in which the cells are kept, but other substances of interest (e.g., neurotransmitter, agonists, or antagonists) can be added to this pipette solution to study the pharmacology of ionic channels.

Whole-Cell Patch Clamp

Patch clamp can be used to obtain an electrical recording of the activity of the entire cell by using the so-called whole-cell recording method. Whole-cell recordings are obtained by breaking the patch of membrane on which the gigaseal has been obtained. This is accomplished by applying negative pressure through the patch pipette, which for this type of recordings will contain a solution very similar to the intracellular medium (Ogden and Stanfield 1994). Once the cell is “opened,” the membrane potential of the entire cell can be controlled and the current measured (voltage clamp) or the membrane potential of the cell can be measured (current clamp).

Compared to traditional sharp electrode techniques, whole-cell patch clamp configurations have a relatively low access resistance (resistance between the electrode and the cell membrane, see Fig. 2a) allowing to resolve smaller currents and reducing the error due to drop in voltage across resistive elements. For these reason, whole-cell patch clamp has become the preferred tool for the study of the electrical

properties of mammalian neurons and neuronal networks (Stuart et al. 1993).

A disadvantage of whole-cell patch clamp over sharp electrode techniques is the risk of washing out the intracellular medium with the patch pipette solution. The dialysis of the intracellular solution is a major limitation for the study of plasticity mechanisms mediated by second messengers. To circumvent this problem, Horn and Marty (1988) introduced a technique called perforated patch, in which antibiotics (such as nystatin) are added to the patch pipette solution to create “holes” on the patched membrane. The artificially created non-ion-specific channels in the membrane are too small to allow macromolecules to diffuse back into the pipette and at the same time ensure a relatively low-resistance electrical connection between the patch clamp system and the interior of the cell.

Excised Membrane Patch Clamp

The need to study quickly changing concentrations of ions or neurotransmitters has led to the use of cell-free patching of membranes. Rapidly pulling the recording pipette away from the cell after the gigaseal is established will often leave a portion of membrane attached to the glass. Doing so in whole-cell or cell-attached configurations will lead to outside-out or inside-out excised membrane patch configurations (see Fig. 2). The main advantage of cell-free recordings is that they allow to study drug binding to both the extracellular and the intracellular domain of the cell by simply modifying the bath solution. However, even when using various tricks to improve the seal, the signal-to-noise ratio of these recording is often quite low, and in some cases, the channel kinetics in excised patch and in cell-attached patch have been reported to be different (Covarrubias and Steinbach 1990).

Modern Developments

Its low access resistance has made whole-cell patch clamp the ideal tool for the injection of

fast currents required for dynamic clamp and action potential clamp. Moreover, the rapid exchange of solution between the patch pipette and the cell allows rapid filling of the neuron with dye and fluorescent indicators. In the last two decades, the improved stability of micro-manipulators allowed researchers to patch cellular compartments (i.e., dendrites, axons, and presynaptic terminals) previously inaccessible to direct electrical recordings and manipulations (Williams and Stuart 2003; Debanne et al. 2011).

Pathological Changes in Peripheral Nerve Excitability

Steven A. Prescott

Neurosciences and Mental Health, The Hospital for Sick Children, Toronto, ON, Canada
Department of Physiology, University of Toronto, Toronto, ON, Canada

Definition

Reversing pathological changes in nerve excitability is an important clinical goal. Achieving that goal requires identification of the underlying molecular changes and a clear understanding of how excitability is altered on the basis of those changes. Computational modeling plays an important role in addressing those issues. One approach involves incorporating known or suspected ion channel changes into normal axon models to test whether such changes can explain pathological changes in excitability. An alternative approach involves reproducing the pathological changes in excitability and then working backward to identify which ion channel changes may be involved.

Detailed Description

Nerve Injury: From Clinical Symptoms to Molecular Pathology

Peripheral nerves comprise axons of sensory, motor, and autonomic neurons. The signs and symptoms of nerve injury reflect which of those axons are damaged. The most obvious consequence of nerve injury is a loss of normal function which, for example, could manifest as numbness in the case of mechanosensory axons or paralysis in the case of motor axons. A less obvious

consequence of nerve injury is gain of function resulting from axonal hyperexcitability, manifesting as pain and spasticity for mechanosensory and motor axons, respectively. Nerve injury is thus associated with both negative and positive symptoms, where the proportion of each depends on the nature and extent of axonal damage and the recovery therefrom. This poses a clinical dilemma insofar as treatments intended to diminish negative symptoms often exacerbate positive symptoms and vice versa (Bowe et al. 1987).

Axonal damage can arise from trauma, through diseases such as diabetes and demyelination disorders, and via toxicity by chemotherapeutics and antiretrovirals (Baron et al. 2010). It remains unclear whether hyperexcitability is a direct consequence of axon damage or a compensatory response to it. In many cases, injury dysregulates the expression, trafficking, and/or insertion of ion channels. However, the homeostatic response to injury may, by overcompensating, lead to yet other problems. This is easiest to appreciate in the context of demyelination disorders where demyelination exposes axon membrane that is not normally involved in saltatory spike propagation – when the spike jumps from one Node of Ranvier to the next – but now must contribute to continuous spike propagation. Increasing the excitability of this newly exposed membrane by increasing the density of sodium channels and/or decreasing the density of leak channels can rescue the propagation failure, but excessive changes can result in hyperexcitability and ectopic spiking, including pathological patterns such as afterdischarge and spontaneous bursting (Calvin et al. 1982; Coggan et al. 2010). Notably, most of the axon is normally involved only in propagating spikes, not initiating them; accordingly, spike initiation at an atypical location, as often occurs at the site of damage, is termed “ectopic.”

Dozens of different ion channel subunits are up- or downregulated after nerve injury (LaCroix-Fralish et al. 2011). Some of those changes contribute to increasing excitability, whereas others counterbalance the former (i.e., decrease excitability). That said, many ion channel changes may have no effect on excitability but are

nonetheless correlated with excitability changes because they co-occur with changes in other “relevant” ion channels. Computational modeling plays an important role in deciphering causal relationships.

Modeling Changes in Axonal Excitability

It goes without saying that models of normal axons can be adapted to investigate injured axons. The more interesting discussion is how to use such models to investigate the sequence of events following injury. One approach is to test which molecular changes, acting alone or together, cause a pathological change in cellular excitability. This is referred to here as a *bottom-up approach*. Alternatively, one can use a *top-down approach*: using modeling to identify abstract mechanistic explanations for the altered excitability and then working backward from there to identify which observed molecular changes are causal. These two approaches will be illustrated by modeling efforts aimed at deciphering changes in somatosensory afferent excitability triggered by nerve injury and thought to contribute to chronic neuropathic pain.

Amongst somatosensory afferents, large diameter myelinated fibers have been shown to become hyperexcitable after nerve injury. These same fibers have been shown to mediate certain aspects of neuropathic pain, namely, hypersensitivity to normally innocuous mechanical stimulation. Hyperexcitability in those fibers has therefore been a significant focus of research. Injury to these axons produces a characteristic triad of qualitative changes in excitability: (1) altered spiking pattern, (2) membrane potential oscillations (MPOs), and (3) spontaneous bursting (Fig. 1).

On the one hand, computer models of this process are tightly constrained phenomenologically: they must reproduce the entire triad of pathological excitability changes. On the other hand, models are only loosely constrained mechanistically: our understanding is very incomplete with respect to which channels are expressed, let alone what the density is before vs. after injury. This allows for different models that provide different

Pathological Changes in Peripheral Nerve Excitability, Fig. 1 Reproduction of injury-induced excitability changes in a simple computer model. (a) Response evoked by sustained current injection switches from a single, onset-only spike under control conditions to repetitive spiking under neuropathic conditions. Membrane potential oscillations (b) and bursting (c) are also seen under neuropathic conditions (Modified from Rho and Prescott (2012). See Liu et al. (2002) for experimental data)

possible mechanistic explanations, thereby providing alternative testable hypotheses. For example, it had been assumed that the MPOs were responsible for the repetitive spiking and bursting; however, recent modeling has suggested an alternative explanation, as will be described below. In any case, the ultimate goal is to explain which of the various up- or downregulated ion channel subunits are responsible for this pathological pattern of axon excitability.

A bottom-up approach to this problem involves starting with a normal axon model and then adding or modifying ion conductances in an effort to reproduce the triad of pathological

excitability changes. Following this sort of approach, Kovalsky et al. (2009) reproduced pathological excitability by incorporating a set of sodium conductances that inactivated with rapid, intermediate, or slow kinetics. Including a range of inactivation kinetics improved upon an earlier model (Amir et al. 2002) by allowing the model to expand the voltage range across which MPOs were observed. Although successful in that respect, the MPOs in this model were characterized by an extremely narrow frequency band that was unlike experimentally observed MPOs, which show a broad peak in the power spectrum. These results suggested that upregulation of multiple different sodium channels (i.e., with a range of inactivation kinetics) is sufficient to produce MPOs and the associated changes in spiking. However, the potential role of other ion channels remained open, as did the mechanistic explanation for MPOs.

A top-down approach revealed a different, and arguably more complete, picture. Attempting to reproduce the same triad of excitability changes, Rho and Prescott (2012) started with a simple model that comprised a fast activation variable and a slow recovery variable. By systematically varying each parameter to test how excitability was altered, they found that many different parameter changes were capable of producing equivalent changes in excitability. Furthermore, because the model was two-dimensional (i.e., comprised only two state variables), it was amenable to nonlinear dynamical analysis. Phase plane and bifurcation analysis showed that qualitative changes in excitability arose from a qualitative change in the interaction between fast and slow ion channels. Under normal conditions, spikes were initiated through a quasi-separatrix crossing (Prescott et al. 2008). By contrast, under pathological conditions, spikes were initiated through a subcritical Hopf bifurcation. This single change in spike initiation mechanism could account for all three components of the neuropathic triad. Repetitive spiking occurred when stimulation exceeded the intensity needed to cause the Hopf bifurcation. Bursting occurred when a slow process like adaptation caused the system to drift back and forth across the

bifurcation point and its associated region of bistability. MPOs occurred because of noise-induced oscillations that developed when stimulation intensity was just below the intensity needed to cause a Hopf bifurcation.

Mechanistically, the Hopf bifurcation destabilized the fixed point. Because that fixed point was a focus, trajectories tended to spiral around the fixed point when that point was only weakly stable. Therefore, when the system was intermittently displaced from its weakly stable fixed point by noise, it would return to its fixed point via damped oscillations. According to this explanation, MPOs do not cause repetitive spiking; instead, MPOs and repetitive spiking are simply two different manifestations of the same dynamical process, namely, a subcritical Hopf bifurcation. MPOs in this model required noise. This illustrates an important point: although noise is ubiquitous in biological systems, its absence from many computer models can lead to certain mechanisms being overlooked. Importantly, noise-induced MPOs are characterized by a broad peak in the power spectrum, comparable to what is seen experimentally.

The observation that varying different parameters could give rise to the same excitability changes is also very important. The fast- and slow-activating conductances included in this simple model each represent multiple conductances with similar kinetics (Kepler et al. 1992); in other words, the simple model is a reduced version of a more biologically detailed model. A functionally equivalent yet higher-dimensional, detailed model would have a much greater number of parameters whose variation could cause neuropathic excitability. There is, in other words, a many-to-one mapping between molecular changes and a switch in spike initiation mechanism capable of causing neuropathic excitability. This many-to-one relationship constitutes *degeneracy* (Edelman and Gally 2001; Marder and Taylor 2011). If multiple different molecular changes are sufficient to cause neuropathic excitability, and multiple sufficient changes codevelop after nerve injury, then no single change will be necessary for the development of neuropathic excitability (Ratté et al. 2014). This is problematic

from a therapeutic perspective insofar as the ideal scenario for drug development is to have a single target that is necessary and sufficient for the pathological change. In this scenario, the pathology can be prevented or reversed when that target is hit by the appropriate drug. By contrast, if the molecular basis for neuropathic excitability is highly degenerate, then multiple different ion channels must be simultaneously targeted for the therapeutic intervention to be effective. Alternatively, one should step back to ask if there is a high-order, nondegenerate modulatory process that is coordinately regulating multiple ion channels and which would therefore constitute a better drug target.

Pros and Cons of Each Approach

Strictly speaking, the bottom-up approach requires knowledge (or reasonable suspicion) of which ion channels are changed and by how much. This information, however, remains largely unknown and is difficult to obtain through current experimental technologies. Alternatively, the bottom-up approach can be used in an exploratory fashion to identify which ion channels, if altered, could account for the change in excitability. This is essentially what Kovalsky et al. did in their study. On the other hand, a modeling study by Boucher et al. (2012) provides a good example in which a specific injury-induced change that has been quantified experimentally, namely, a leftward shift in the voltage-dependency of sodium channel activation and inactivation, was tested in a model in order to determine the effects of such a change on cellular excitability. A bottom-up approach is also very useful for testing how two or more molecular changes might interact if they occurred together.

The top-down approach is especially useful when the pattern of hyperexcitability is well described but the potential molecular causes are not, as is the case for the triad of neuropathic changes described in Fig. 1. Ideally a top-down model can reduce the phenomenology to a dynamical process within a low-dimensional space, as in the model of Rho and Prescott (2012). This provides the ability to explore the

dynamics using classical dynamical system tools to provide direct insight into the causes of pathology and relationships between different pathological manifestations.

Constructing a model that exhibits the desired pattern of hyperexcitability is an important goal for both modeling approaches. This is especially true for the top-down approach insofar as obtaining that model is a necessary first step before any other testing can be conducted. If the phenomenology of interest can be captured in a relatively simple model, then the top-down approach is feasible. It is notable that even quite simple models can manifest complex phenomena on the basis of nonlinearities. This is exemplified by the triad of neuropathic excitability changes discussed above. Nonetheless, other phenomena may require more complicated, higher-dimensional models. Finding the right parameter set for such a model can be extremely difficult. Furthermore, it is likely that there will be more than one appropriate set of parameters (degeneracy). This can be addressed through brute force modeling, in which a broad range of different parameter combinations is exhaustively tested. Alternatively, one can use genetic (or evolutionary) algorithms to help find appropriate parameter combinations more efficiently. But indeed, knowing that there is not a unique solution – that the molecular basis for cellular hyperexcitability is highly degenerate – is itself very important.

Conclusions

Nerve injury can cause a variety of changes in axonal excitability. Those changes can have debilitating consequences in terms of altered sensory, motor, and autonomic function, and so deciphering the basis for those changes is an important goal. Computer modeling can contribute significantly to delineating how such changes arise and how to strategically reverse them. Results from modeling studies indicate that changes in ion channel function or expression can qualitatively alter how action potentials are generated, which in turn affects various aspects of

excitability. The observation that equivalent excitability changes can arise on the basis of very different molecular changes is also very important.

Pattern Formation in Neural Population Models

Definition

Experimental studies have shown that neural population activity may exhibit certain well-structured spatiotemporal patterns, which reflect the properties of the neurons in the underlying network. The aim of neural population models is the reconstruction of such experimentally observed patterns or their prediction.

Detailed Description

Spatial patterns in neural populations and their temporal evolution have been observed experimentally in different neural structures. They emerge due to a strong interplay between the spatial physiological structure of the population, the intrinsic time scales, and the nonlinear interaction of elements. For instance, in a neural field model, these elements typically are the spatial axonal connectivity topology, the mean synaptic time scales, the nonlinear transfer function, and the additional nonlinear interactions such as synaptic depression.

One of the most important questions in the study of pattern formation is what the observed

pattern tells us about the underlying system or, put differently, why a certain pattern occurs. In this context, it is important to distinguish stimulus-induced patterns and spontaneous patterns.

Stimulus-Induced Patterns

Neural populations are subjected to external inputs originating, e.g., from other neural areas or from electric stimulation by electrodes in physiological experiments. In the absence of external stimulation, the neural population may not exhibit any specific spatial pattern. For instance, the neural activity may be identical at each spatial location. Now inducing a localized stimulation for a longer time may reveal spatial structures or even induce complex spatio-temporal patterns. Figure 1 shows the effect of a localized stimulation on a neural field with hexagonal spatial interactions and finite axonal transmission delay. One observes that the center stimulus activates the neural population by a slow spread of activity. Since the spatial kernel exhibits excitation on a hexagonal lattice, this lattice emerges during the stimulation.

Considering a simpler rotational-invariant interaction kernel, finite axonal transmission speed, and a rotational-invariant stimulation, one does expect a spatial structure with the same rotational-invariant symmetry. Figure 2 shows the neural field activity retaining the spatial stimulus symmetry. However, the external stimulation induces oscillations of the activity bump although the stimulation is constant in time. The reason for this oscillation is the instability of the temporally constant activity bump induced by the finite axonal transmission speed which represents delayed interactions between neurons. It is important to mention that a similar stimulus in another neural field with different nonlinear actions may also lead to a break of rotational-invariant symmetry (Bressloff 2012).

Spontaneous Patterns

If external stimuli are small, they do not evoke patterns as described in the previous section. However, spatial structures may occur

nevertheless. This is possible if a resting state constant in time becomes unstable. In the presence of small random fluctuations, e.g., in physiological parameters or the external input, the system leaves the vicinity of the resting state and approaches a new stable state. The existence of such a new stable state is strongly determined by both by the nonlinear dynamics close to the stationary state and the spatial interactions in the population (Bressloff 2012). Close to the bifurcation point, the linear dynamics of the resting state determines the approximate dynamics of the new stable resting state. For instance, if the resting state loses stability and the system leaves the vicinity of the state while oscillating, then the new stable state oscillates as well with a similar

frequency. Moreover, if the system prefers a certain spatial structure while losing stability, this spatial structure shows up in the new resting state.

Initial Constant State

First, let us consider a spatially constant stationary state which is unstable (Fig. 3). Small perturbations push the system from this unstable state, and it then evolves according to the intrinsic properties of the unstable state. In the case of the field in Fig. 3, the neural field involves transmission delay between neurons, and the stationary state is oscillatory unstable. Hence it oscillates while approaching the new stable state, which is a constant spatial bump. Since the bump is stable, the system remains in this state. It is important to note that the initial unstable state was constant and the final stable state has a different spatial shape.

The new stable state may even exhibit a more complex pattern. One of the simplest but non-trivial cases is a Turing pattern that is constant in time but exhibits a regular spatial pattern with a single spatial frequency. The spatial pattern shown in Fig. 4 emerges from a constant state, and the selection of the spatial frequency results from the nonlinear spatial interaction in the system; see, e.g., Bressloff (2012) and Hutt et al. (2003) for further explanations.

Pattern Formation in Neural Population Models, Fig. 6 Turing-Hopf (codimension-2) bifurcation in a two-dimensional neural field (Taken from Fig. 5 in Steyn-Ross et al. (2013), with permission)

Pattern Formation in Neural Population Models, Fig. 7 An initial circular stimulation triggers the circularly spreading activity front followed by the onset of an oscillation with radius-dependent phase lag. This phase lag

leads to the impression of a pulsatile activity with rings spreading from the center. The neural field under study considers synaptic depression (Taken from Fig. 14 in Bressloff (2012), with permission)

Turing instabilities are known to result from locally excitatory-laterally inhibitory interactions. This interaction enforces the local activity of neurons and reduces their activity in the neighborhood and hence prefers localized structures. Historically, this interpretation has been formulated first for partial differential equation models, where it holds true in most cases. However, it can be shown that this interaction type might lead to instabilities which exhibit a periodicity in space and time, so-called Turing-Hopf bifurcations. If the change of a single physiological parameter destabilizes a spatially constant state and a spatially and temporally oscillatory pattern emerges, then this instability is called wave instability or

sometimes codimension-1 Turing-Hopf instability, cf. Fig. 5.

If the change of one physiological parameter leads to a Turing bifurcation and the synchronous change of another parameters renders the system oscillatory unstable (Hopf instability), then two instabilities occur synchronously and the Hopf and Turing patterns overlap. This bifurcation is called Turing-Hopf codimension-2 bifurcation; cf. Fig. 6.

Initial Pattern

For initial constant states, the new stable pattern reflects the intrinsic spatial interactions. If the

Pattern Formation in Neural Population Models, Fig. 8 The localized initial triangular-shaped activity breaks the rotational symmetry and induces the growth of

a complex pattern (Taken from Fig. 5 in Owen et al. (2007), with permission)

initial state has a certain spatial structure, the new stable state may take over this pattern or slightly modify it. Figure 7 shows the temporal evolution of a rotationally invariant structure, whose symmetry follows from the initial structure. However the involved nonlinearities lead to a complex spatiotemporal evolution while retaining the initial rotational symmetry.

This concept of retaining the initial symmetry is also present in Fig. 8 in the first part of the transition phase (until time = 80), where the evolving structure still has the triangular symmetry of the initial state. However, the further the system moves away from the initial state, the less pronounced is the initial structure, and the new complex structure does not resemble anymore the initial state.

Lyapunov Functional

In order to learn more about the transients from an unstable to a stable state, e.g., about the time when

Pattern Formation in Neural Population Models, Fig. 9 The Lyapunov functional $E[u]$ subjected to time during the transient phase from an unstable initial state (circle) to a circle of isolated bumps (Taken from Fig. 12 in Owen et al. (2007), with permission)

the system reaches the stable state, it is useful to compute the Lyapunov functional for neural fields $\mathcal{L}$ (French 2004). The functional $\mathcal{L}$ is computed at each instant taking into account the systems

properties and spatial activity. It decreases in time and reaches its local minimum when the state reaches a new stable state. For illustration, one can think of a high-dimensional landscape whose altitude is given by $\mathcal{L}$. Figure 9 shows the Lyapunov functional during the temporal evolution of a neural field, and the final state is reached when the Lyapunov functional does not change anymore.

Perception, Bayesian Models of

Ulrik R. Beierholm

Psychology Department, Durham University, Durham, UK

Centre for Computational Neuroscience and Cognitive Robotics, University of Birmingham, Birmingham, UK

Definition

Bayesian models of perception use optimal statistical methods to perform inference based on perceptual data. These models are used in computational neuroscience and cognitive psychology to explain how the nervous system processes perceptual information.

Detailed Description

Bayesian inference provides the optimal statistical inference about unknown properties given a

Further Reading

Amari S (1977) Dynamics of pattern formation in lateral-inhibition type neural fields. *Biol Cybern* 27:77–87

stochastic process. Bayesian models of perception work under the hypothesis that the nervous system uses perceptual information as if it was able to optimally process the information according to a Bayesian inference model. The majority of models propose how the nervous system processes discrete cues (flash of light, auditory beep), but models have also been proposed for, e.g., learning in perception.

All Bayesian models start by specifying the generative process along with the associated probability distributions (e.g., prior and likelihood distributions). Using Bayes' rule (examples below), the generative process is reversed to an inference process to find the posterior probability distributions over the variables of interest. If a single variable estimate is needed (e.g., an experimental subject has to perform a button press), a subjective utility function can be combined with the posterior distribution to find the optimal response, e.g., the mean or the maximum of the posterior.

It is thus implicitly assumed in Bayesian models of perception that the nervous system is able to represent all the variables and the processes in such a Bayesian inference, including the likelihood, prior, decision process, etc.

Effect of Prior Knowledge

The simplest case of perceptual Bayesian inference involves a single cue having been generated from a single source (Fig. 1), e.g., the visual stimuli from a moving object providing some noisy information about the true velocity (Weiss et al. 2002). The task of inferring the true velocity of the object, X , requires the use of Bayes' theorem

$$P(X|V) \propto P(V|X)P(X) \quad (1)$$

which states that the posterior probability of the true property conditional on the observed variable $P(X|V)$ is proportional to the product of the likelihood function $P(V|X)$ and the prior $P(X)$.

Thus, the current sensory information and its associated uncertainty (given by the likelihood)

Perception, Bayesian Models of, Fig. 1 Simple Bayesian model for inference based on one cue. The *gray circle* indicates an observed variable, while *white* is unobserved

combine with previous information (given by the prior) to produce the new estimate of the unknown variable.

Usually, the prior and likelihood will be specified in a way such that the posterior has the same analytical form as the prior (i.e., conjugate), e.g., by using Gaussian probability distributions.

Once the posterior probability distribution for X is specified, $P(X|V)$, a subject is assumed to make a choice, $\hat{X}$, based on, e.g., the mean or maximum of the distribution (dependent on the subjective utility function specified).

Cue Integration

When multiple cues provide independent information about the same source (see Fig. 2), it is optimal to combine the information from the two sources (Knill and Pouget 2004), e.g., haptic and visual information about the width, X , of an object

$$P(X|V, H) \propto P(V|X)P(H|X)P(X) \quad (2)$$

under the assumption that the uncertainty in the two percepts of the two stimuli are independent given the source.

Thus, the two current sensory cues and their associated uncertainty (given by the likelihoods) combine with previous information (given by the prior) to produce the new estimate of the unknown variable. When the likelihoods and priors are represented by Gaussian probability distributions,

Perception, Bayesian Models of, Fig. 2 Bayesian model for inference based on two cues

$N(\mu, \sigma^2)$, the posterior also becomes a Gaussian probability distribution, $N(\mu_X, \sigma_X^2)$, with the mean and variance specified through weighting the individual stimuli by their uncertainty:

$$\begin{aligned} \mu_X &= \frac{\mu_V/\sigma_V^2 + \mu_H/\sigma_H^2}{1/\sigma_Z^2}, \quad \sigma_X^2 \\ &= \frac{1}{1/\sigma_V^2 + 1/\sigma_H^2} \end{aligned} \quad (3)$$

Accordingly, subjects can decrease their perceptual uncertainty (σ_X^2 is smaller than either σ_V^2 or σ_H^2) and should rely more on the stimulus with smaller uncertainty. This linear weighted contribution has been tested for many combinations of either multi- or uni-sensory cues with generally good correspondence for small discrepancies between the cues (Trommershauser et al. 2011).

Explaining Away

Another potential way of cue interaction comes from a model that allows the inferred variability about one cue to be able to “explain away” the variance of another cue (Kersten et al. 2004) due to the generative structure (see Fig. 3). An example is the estimation of the shape of an object (e.g., concave or convex) given the visual image and a cue toward the location of the source of lighting:

Perception, Bayesian Models of, Fig. 3 Bayesian model for inferring a variable using explaining away

$$P(Y|V, W) \propto P(Y) \sum_X P(W|X) P(V|X, Y) P(X) \quad (4)$$

The knowledge about a cue for lighting direction W restricts the range of values for the true direction of lighting X in turn allowing a better estimate of the shape Y .

This model has been used to explain a number of phenomena in human vision (Knill and Richards 1996) where different cues influence the percept of a visual scene.

Causal Inference

When multiple sources and multiple cues are available in the world, a problem of cue assignment becomes apparent (Shams and Beierholm 2010). One Bayesian solution to this is to infer the potential causal structure that gave rise to the stimuli observed (see Fig. 4). For example, if two observed stimuli (V and A) may have arisen from either the same sources or separate sources, Bayesian inference can be used to infer the most likely causal structure:

$$P(C|V, A) = \frac{P(V, A|C)P(C)}{\sum P(V, A|C)P(C)} \quad (5)$$

Once a probability for each causal structure has been inferred, the distribution of any unknown variable, e.g., X , can be found:

$$P(X|V, A) = \int P(X|V, A, C) P(C|V, A) dC \quad (6)$$

Perception, Bayesian Models of,

Fig. 4 Bayesian model for causal inference based on two cues and two possible causes

$$= P_{C=1}(X|V, A)P(C = 1|V, A) + P_{C=2}(X|A, V)P(C = 2|V, A). \quad (7)$$

where $P_{C=1}(X|V, A)$ is the posterior probability of X given A, V according to the single cause model ($C = 1$), similarly for $P_{C=2}(X|V, A)$.

Getting an estimate of $\tilde{X}$ such as the mean of the posterior is thus equivalent to performing model averaging:

$$\tilde{X} = P(C = 1|V, A)\tilde{X}_{C=1} + P(C = 2|V, A)\tilde{X}_{C=2} \quad (8)$$

where $\tilde{X}_C$ indicates the optimal estimate according to the causal structure C (e.g., see the solutions for one or two sources above). Several models have been proposed that although structurally different also try to explain subject behavior dealing with multiple cues and sources (see, e.g., Ernst (2006)).

Other Bayesian Models of Perception

Apart from models of cue combinations, other studies have also suggested Bayesian models for, e.g., visual learning (Orbán et al. 2008; Feldman 2001).

[Learning in feed-forward neural networks](#)

Definition

The perceptron is a neural network based in the nonlinear McCulloch-Pitts neuron model. It is composed of a single layer of N neurons (presynaptic) that are connected by means of uni-directional or feed-forward connections, or synapses, to a unique (postsynaptic) neuron (see Fig. 1). This “single-layer” perceptron is the simplest feed-forward neural network. On the other hand, the perceptron learning algorithm is the procedure by which this network adjusts its connection intensities, or synaptic weights, and the postsynaptic neuron threshold (also known as bias) to correctly classify a given number of inputs into desired output values. The perceptron learning algorithm was proposed by F. Rosenblatt (1958). It is the first example of the so-called supervised learning, that is, learning with a teacher, since the connection intensities and the threshold are adjusted according to the error obtained in the classification of the inputs. The perceptron learning algorithm can be used to implement simple Boolean functions such as AND and OR but fails to correctly implement the XOR (exclusive-or) Boolean function (see below). In this last case, it is necessary to include additional layers of neurons, denoted as hidden layers (Peretto 1992). The network architecture, functioning, and use of

Rosenblatt perceptron is similar to other artificial neural network developed at the same time and known as “Adaline” proposed by B. Widrow and T. Hoff (1960).

Detailed Description

The perceptron is a binary classifier which maps an input X (a vector with N real components) to an output value $Y(X)$ (a single binary value) in the form (see Fig. 2):

$$Y(X) = \text{sign}(W \cdot X + B) = \begin{cases} 1 & \text{if } W \cdot X + B > 0 \\ -1 & \text{Otherwise} \end{cases}, \quad (1)$$

where W is a vector of N real-valued synaptic weights, $W \cdot X$ is the dot product (which therefore computes a weighted linear combination of the inputs), and B is a “bias” term, that is, a constant term that does not depend on any input value and usually is related with a postsynaptic neuron threshold ($B = -\theta$).

In the case of a binary classification problem, the output value $Y(X)$, namely 1 or -1 , is used to classify X into one of two classes, C_1 or C_{-1} , respectively. These two classes then correspond

Perceptron Learning, Fig. 1 Scheme showing the architecture of a single-layer (left) and multiple-layer (right) perceptron with a hidden layer

Perceptron Learning, Fig. 2 Perceptron neural network with input and weights vectors X and W (left) and its transformation into a perceptron with extended input $\bar{X}$ and weights $\bar{W}$ vectors (right)

to two different decision regions in which the N -dimensional space of input vectors is separated by a hyperplane, denoted as decision boundary, and defined by the identity:

$$W \cdot X + B = 0.$$

The effect of the bias B is to alter the position of the decision boundary by means a shift around the position in the input space defined by the vector $X = 0$ without altering the orientation of this hyperplane.

For proper operation of the perceptron, the two classes of inputs vectors, C_1 and C_{-1} , must be linearly separable. That is, the input vectors X to be classified must be sufficiently separated from each other in the N -dimensional space to ensure that the decision surface consists of a hyperplane. On the contrary, if C_1 and C_{-1} are not linearly separable, the perceptron learning will never reach a point where all input vectors are classified properly. A well-known example of nonlinearly separable classes of input vectors where the perceptron algorithm fails to correctly classify the inputs is the Boolean exclusive-or (XOR) problem where the decision boundary is not a hyperplane.

Algorithm Description

The algorithm is able to determine the discriminant plane equation from a given number of correctly classified examples. For a better

understanding of the algorithm, it is more convenient to extend the dimensionality of the input and weights vectors as follows (see Fig. 2):

$$\begin{aligned} X &= (X_1, \dots, X_N) \rightarrow \bar{X} = (X_1, \dots, X_N, 1) \\ W &= (W_1, \dots, W_N) \rightarrow \bar{W} = (W_1, \dots, W_N, B). \end{aligned}$$

In this way, the bias is interpreted as a synaptic weight driven by a constant input equal to 1. Using this new notation, the condition in Eq. (1) for mapping the extended inputs $\bar{X}$ in the two classes C_1 y C_{-1} now becomes:

$$\begin{aligned} Y(\bar{X}) &= \text{sign}(\bar{W} \cdot \bar{X}) \\ &= \begin{cases} 1 & \text{if } \bar{W} \cdot \bar{X} > 0 \\ -1 & \text{Otherwise} \end{cases}, \end{aligned} \quad (2)$$

and the decision boundary is now given by the identity:

$$\bar{W} \cdot \bar{X} = 0.$$

Now select a set of extended inputs vectors $\bar{X}$ that will be considered as the training set, and assume that are correctly classified in class C_1 or in class C_{-1} . This means that there exists an extended weight vector $\bar{W}$ such that:

$$\begin{aligned} \bar{W} \cdot \bar{X} &> 0 & \text{if } \bar{X} \text{ belongs to class } C_1 \\ \bar{W} \cdot \bar{X} &\leq 0 & \text{if } \bar{X} \text{ belongs to class } C_{-1}. \end{aligned}$$

The perceptron learning algorithm then is performed as follows:

1. Initialization: An extended weight vector $\overline{W}_0$ is generated randomly at $t = 0$.
2. Test: At any iteration t , choose at random a training vector $\overline{X}$ from the training set and compute $\overline{W}_t \cdot \overline{X}$. If $\overline{X}$ is correctly classified with the current vector of weights $\overline{W}_t$, then choose:

$$\overline{W}_{t+1} = \overline{W}_t$$

and go to step 2. Otherwise:

- (a) if $\overline{W}_t \cdot \overline{X} > 0$ and $\overline{X}$ belongs to C_{-1}

$$\overline{W}_{t+1} = \overline{W}_t - \eta \overline{X}$$

and go to step 2,

- (b) if $\overline{W}_t \cdot \overline{X} \leq 0$ and $\overline{X}$ belongs to C_1

$$\overline{W}_{t+1} = \overline{W}_t + \eta \overline{X}$$

and go to step 2.

The parameter $\eta > 0$ describes the rate of learning of each iteration. This algorithm corrects the extended weight vector (weights and bias) whenever one of training vectors belonging to C_1 or C_{-1} has not been classified correctly. The perceptron convergence theorem guarantees that if the training set is linearly separable into C_1 or C_{-1} , then the weights vector $\overline{W}$ is updated only a finite number of times. The algorithm can be stopped when all vectors are correctly classified.

Since the output $Y(\overline{X})$ is binary, the algorithm can be written in a simpler way as follows:

1. Initialization: An extended weight vector $\overline{W}_0$ is generated randomly at $t = 0$.
2. Test: At any iteration t , choose at random a training vector $\overline{X}$ from the training set, and compute $\overline{W}_t \cdot \overline{X}$ and the binary output $Y(\overline{X})$ according to Eq. (2). Then update the weights according to the rule:

$$\overline{W}_{t+1} = \overline{W}_t + \frac{\eta}{2} [Y^c(\overline{X}) - Y(\overline{X})] \overline{X} \quad (3)$$

and go to step 2

where $Y^c(\overline{X})$ represents the correct output to the training input vector $\overline{X}$.

The weights updating rule (3) is similar to the so-called “Delta rule” or “backpropagation” algorithm first introduced in the “Adaline” learning algorithm (Widrow and Hoff 1960). In this sense, the perceptron can be considered as a particular case of the Adaline neural network for the case of binary outputs $Y(\overline{X})$ instead of a differentiable and, in general, nonlinear, real-value function $Y(\overline{X})$ of the inputs considered in the Adaline neural network. Since in this last case $Y^c(\overline{X})$ never exactly match the correct outputs, $Y^c(\overline{X})$ is necessary to introduce an error function $E = \frac{1}{2} [Y^c(\overline{X}) - Y(\overline{X})]^2$ and a convergence criterion over this error function for the correct classification of the inputs. In the case of the perceptron, however, one directly has $E = 0$ when the inputs $\overline{X}$ are correctly classified since $Y(\overline{X})$ and $Y^c(\overline{X})$ are binary, so no convergence criterion over E is needed.

The “Delta rule” in Adaline is obtained when weights are modified during learning trying to minimize the error E in the output of the network through a gradient descent procedure, that is,

$$\overline{W}_{t+1} = \overline{W}_t - \eta \nabla_{\overline{W}} E$$

which takes the form given by Eq. (3) for the perceptron.

Storage Capacity of Perceptrons

The maximum number P of random input vectors X^μ , $\mu = 1, \dots, P$ that can be trained and correctly classified in a perceptron with an input layer of N neurons was analytically computed by E. Gardner (1988) using a statistical mechanics framework and assuming that the weights were constrained such that $\sum_j \overline{W}_j^2 = N$. Within this framework, it is assumed that a training vector is correctly classified when the product:

$$Y(\overline{X}^\mu) \frac{1}{\sqrt{\sum_j \overline{W}_j^2}} (\overline{W} \cdot \overline{X}^\mu) > K,$$

being $K > 0$ a measure of the basin of attraction of each input vector X^μ . The resulting maximal storage capacity $\alpha_c = P/N$ was:

$$\alpha_c = \left[\int_{-K}^{\infty} \frac{e^{-\frac{z^2}{2}}}{\sqrt{2\pi}} (z + K)^2 dz \right]^{-1}$$

which gives $\alpha_c = 2$ for $K = 0$, a result previously obtained by T.M. Cover (1965).

Perceptual Decision-Making

Christopher K. Hauser and Emilio Salinas
Department of Neurobiology and Anatomy, Wake Forest School of Medicine, Winston-Salem, NC, USA

Definition

Perceptual decision making is the process by which sensory information is used to guide behavior toward the external world. This involves gathering information through the senses, evaluating and integrating it according to the current goals and internal state of the subject, and using it to produce motor responses. In contrast to choice behavior and decision making in general, which are closely related concepts traditionally studied by psychologists, behavioral ecologists, and economists, perceptual decision making emphasizes the role of sensory information in directing behavior (e.g., during a choice). Thus, within neuroscience, the goal is to reveal the computational mechanisms whereby neural circuits encode, store, and analyze perceptual signals; combine them with other behaviorally relevant information; and use them to resolve conflicts between competing motor plans.

P

Detailed Description

Studies in perceptual decision making aim to explain the behavior of a subject in terms of the activity of relevant cells and molecules in its nervous system. This requires not only methods from psychology (to characterize behavior) and neurophysiology (to measure and record neuronal activity) but also mathematical and analytical methods to bridge the results at the two levels. So, behavior, neurophysiology, and computational modeling are three important themes that are interleaved in the rest of this entry.

Historically, the foundations of the field were clearly laid out by the 1960s, with some notable studies strongly integrating the three elements just

mentioned (Werner and Mountcastle 1963, 1965; Werner 1980). However, these early studies had two main limitations: first, they compared sensory experiences in one system, humans, with neural events evoked by similar stimuli but in different sensory systems, i.e., those of various anesthetized animals; and second, although many sophisticated analytical tools such as information theory and signal detection theory were already in use, their applicability was limited because cheap, powerful computers were not yet available. Contemporary studies, in contrast, typically combine psychophysical results with neurophysiological data obtained simultaneously from the same subject (Parker and Newsome 1998) and are often complemented by a wealth of computational analyses and model simulations.

Perceptual decision making has been investigated in numerous animal models, and each species has its own advantages and limitations. Determining how a specific neuron or population of neurons associated with a given sensory modality contributes to behavior is generally easier both in relatively simple organisms, such as worms (chemosensation), flies (visual motion), or leeches (touch), and in highly specialized ones, such as electric fish (electrosensation), bats, owls, or songbirds (audition). However, much work has traditionally been carried out in monkeys, which exploit multiple sensory modalities and have wide behavioral repertoires, and more recently in rodents. After discussing one example of a simple system and providing some historical and conceptual background, we focus mainly on two computational principles, originally derived from studies in monkeys, that broadly describe how perceptual decisions are generated.

Perceptual Decision Making in a Simple Organism

The nematode *Caenorhabditis elegans* has a nervous system of exactly 302 neurons whose anatomical connectivity, or wiring diagram, is virtually complete. This tiny worm produces movement by undulating its body. Within the confines of a Petri dish, much of its behavior

depends on the balance between two tendencies: whether to continue the bout of relatively straight movement in the current direction (known as a “run”) or to briefly stop and reorient to a new, random direction (i.e., making a “turn”). Individual neurons in this system can be characterized in great detail in terms of their genetic, functional, and molecular properties; thus, dynamic interactions between sensory receptor neurons, interneurons, and motor neurons can be tightly correlated not only with specific behaviors but also with specific neurotransmitters and signaling molecules (Faumont et al. 2012). For instance, avoiding a toxic substance involves relatively few steps: (1) on and off sensory neurons respond to increases or decreases in stimulus strength (substance concentration), respectively. (2) These sensory cells excite or inhibit two pools of opposing chemosensory interneurons, one that acts to maintain the current direction and another that promotes turns. (3) The two interneuron pools then activate two pools of premotor or command interneurons, one that enables forward movement and another that opposes it. (4) Motor neurons, which are distributed along the length of the worm and produce undulatory locomotion, receive input from the command interneurons via chemical synapses and gap junctions. (5) Finally, depending on the relative activations of the two pools of command interneurons, the undulatory movement may either continue, to prolong the current run, or stop, to generate a turn. In essence, the worm behaves as if at each point in time it flipped a coin to decide whether to turn or not, with the environment (sensed via sensory receptor neurons) and its internal state (set by specific neural responses and signaling molecules) determining the bias of the coin. This stochasticity, however, does not hinder identification of the relevant physiological and molecular events. Thus, by observing the worm’s movements, it is possible to precisely identify the cells and molecules that control sensory-driven behaviors (Faumont et al. 2012), say, determining whether a source of food is benign or pathogenic (Zhang et al. 2005) or whether to cross a dangerous region to reach a potential food source (Shinkai et al. 2011). An

essentially complete understanding of how this creature makes sensory-driven decisions seems achievable for any particular behavior.

C. elegans may seem “simple” because, considering all the possible combinations of its sensory inputs, internal states, and motor responses, the resulting space appears large yet manageable. In contrast, species with larger nervous systems are more complex in all respects: they collect much more sensory information per unit time; have a much larger variety of internal states, which will depend strongly on the history of each individual; and may produce many more motor actions. Accordingly, the number and variety of behavioral decisions that, say, a mouse can make – and can *learn* to make – must be astronomical and, for all practical purposes, infinite. To turn such complexity into an evolutionary advantage, an enormous degree of flexibility must be necessary. Indeed, whereas differences between certain, closely related species may often seem striking (e.g., compare a beaver to a naked mole rat), perhaps it is more remarkable that an individual from the same species can tune her perceptual and motor systems to become a pianist, a tennis player, a chess player, or a portrait artist (or, conceivably, all four). In what follows, we will not explicitly address the mechanisms that allow neural circuits to be functionally reconfigured – relatively little is known about this (Salinas and Bentley 2009; Marder 2011; Palmer and Kristan 2011) – but it is important to keep in mind that such flexibility must be a crucial property of all the neural circuits that will be discussed.

Importance of Task Design and Behavioral Context

In terms of behavior, perceptual decision making has been investigated mostly via two-alternative forced-choice tasks in which the subject has to use available sensory information (e.g., visual cues) to make a response. In general, the subject’s performance in such tasks depends on four factors that are at least partially independent and dissociable: (1) the sensory stimuli, (2) the subject’s perceptual capacity, (3) the subject’s motor capacity, and

(4) the subject’s internal state, which is partly set by the behavioral context. The importance of the last point cannot be overstated, as it includes potent modulators such as motivation or attention, which can drastically alter both motor planning and perceptual processing; in fact, context (e.g., thirst) determines whether a subject will cooperate in performing a given task in the first place.

Traditionally, there are four elementary questions that can be asked about the magnitude of a sensation, each one leading to one of four classic psychophysical tasks: “Is there anything there?” defines the detection problem; “What is it?” determines the recognition or identification problem; “How much of it is there?” corresponds to the scaling problem; and finally, “Is this different from that?” defines the discrimination problem – which, historically, is associated with the foundation of quantitative psychophysics (Werner 1980). Through these tasks, early research attempted to find systematic relationships between a stimulus parameter, such as the brightness of a light or the loudness of a sound, and the magnitude of the perceived sensation reported by human subjects. Weber’s law and the logarithmic and power-law relationships proposed by Fechner and Stevens, respectively, are well-known examples of this (Gescheider 1997), but a crucial realization was that such relationships cannot be fully distinguished unless something is known about the neural code interposed between the physical stimulus and the perceived sensation (Johnson et al. 1996). That is, behavioral studies are not enough; to understand perception, one must look at the underlying neuronal activity (Parker and Newsome 1998).

Early attempts to link perception and neurophysiology followed the classic psychophysical methodology. For instance, Werner and Mountcastle (1965) investigated the responses of primary mechanosensory afferents elicited by brief (~400 ms) tactile stimuli generated via a small probe (1 mm diameter tip) indenting the skin. They varied the amplitude of the indentation (0–600 μm), S , and found that, in cats and monkeys, under a variety of experimental conditions, the mechanosensory responses were well described by the relation $R = k S^n$, where R is

the number of action potentials evoked during stimulation, k is a constant, and n is a positive exponent typically smaller than 1. Besides establishing such relationship between physical stimulus and neuronal response, they also noted that magnitude estimates of touch sensations reported by humans under similar experimental conditions were also well fitted by a power law with slightly different k and n parameters. An interesting consequence of these relationships is that “the neural transforms intervening between input and the final verbal description of an introspective magnitude estimation must be linear for the intensive continuum” (Werner and Mountcastle 1965). In other words, when touching the hood of a car to feel whether it is running or not, the subjective intensity of the vibrations reported by a person must be directly proportional to the firing rate of the somatosensory neurons that are activated by the engine’s vibrations. Such proportionality between perceived magnitude and neuronal activity seems to remain true for other stimulus features too, such as the roughness of a surface (Johnson et al. 1996).

In contrast to these early studies, recent experiments are often more ambitious, aiming to investigate how other factors in addition to the physical properties of one stimulus impact perceptual performance. This may be achieved by manipulating reward amounts, stimulus probabilities, or temporal constraints; by introducing probabilistic reward schedules and other uncertainties; or by requiring the subjects to consider multiple stimulus features or cues simultaneously in order to maximize the likelihood of a correct response. Here, the subject has to consider all the task constraints, compute the net values of all the available options, and simply ask “Which option is more desirable?” The investigator then tries to determine how all the identified factors that may impact desirability are internally weighted and how they affect overall performance, the neural responses, and the perceptual judgment itself (Kennerley and Walton 2011; Padoa-Schioppa 2011; Cisek 2012).

Perceptual decisions generally involve the analysis of sensory information and the planning and execution of a motor action, both of which are

affected by task contingencies, even in the simplest cases. For example, when monkeys are trained to look at a single, highly salient target, their eye movements are more accurate and are triggered more rapidly, i.e., with shorter reaction times, or **RTs**, when a large reward is at stake than when a low reward is at stake (Takikawa et al. 2002). So, when motivated, the monkeys make haste without compromising accuracy. It is remarkable that motivation has an impact even on eye movements to single targets, because these are highly stereotyped and relatively effortless. Under somewhat more complicated conditions, when monkeys have to rapidly choose between a target and a distracter and the urgency of the discrimination varies across trials, the impact of the potential reward is more subtle: when a large reward is at stake, the eye-movement responses (i.e., saccadic RTs) become slightly *slower* than when a small reward is at stake, thus providing slightly more stimulus viewing time to the subjects, but the perceptual analysis itself proceeds more rapidly and more accurately for a given amount of viewing time (Shankar et al. 2011). This makes sense because both effects together, slower motor execution and faster/more efficient perceptual discrimination, increase the rate of successful outcomes per unit time in this case. These two examples show that motivation may impact performance in complex ways, not only by speeding up or slowing down the subject’s motor plans, as appropriate, but also by modulating the efficacy of the perceptual evaluation itself. More generally, contextual and internal factors may strongly influence how perceptual information is processed and whether it is taken into account at all (Kawagoe et al. 1998; Palmer and Kristan 2011).

Elementary Computational Principles in Perceptual Decision Making

Research on perceptual decision making in non-human primates has revealed two general computational principles that seem to apply across species, modalities and task conditions: one, that perceptual decisions depend on a comparison

between pools of neurons that are selectively tuned for the sensory features that distinguish each option, and two, that the influence of sensory information on the circuits that directly generate motor choices is not instantaneous, but rather accumulates gradually over time (Gold and Shadlen 2007; Heekeren et al. 2008). So, consider, for instance, a driver that reaches an intersection and must decide whether to step on the brake or the accelerator based on standard traffic light rules, i.e., green light $\rightarrow$ go, red light $\rightarrow$ stop. First, when the intersection is reached, competing motor plans for pressing the brake and the accelerator are initiated; once the stoplight is in view, groups of color-sensitive visual neurons are activated; the responses of red- and green-selective neurons then bias the competition in favor of the motor plans for pressing the brake or the accelerator, respectively; over time, one of these plans – namely, the one congruent with the actual color of the stoplight – increases much more than the other, until at a certain point (when activity exceeds a threshold level) it triggers the corresponding motor action. Several key issues are easy to appreciate from this example: how does the decision-making process change when the sensory information is degraded (e.g., the driver forgot her glasses), when the urgency of the decision increases (e.g., the car approaches the intersection very fast), when one of the actions is strongly preferred (e.g., the driver is in a hurry), or when the motor reactions are slow (e.g., the brake pads in the car are worn out)? All of these situations have experimental counterparts. We now discuss experimental results that support this general framework and illuminate specific aspects of the process whereby sensory information guides a motor choice.

Discriminating Randomly Moving Dots

Much of what is known about the two principles just mentioned derives from single-neuron recordings in awake monkeys trained to perform perceptual decision-making tasks. In such tasks, the animal is presented with a sensory stimulus (images displayed on a monitor, in the case of

vision), it must then analyze it according to the rules of the task and must report its judgment by making a particular motor action (Parker and Newsome 1998; Romo and Salinas 2001). One of the most studied tasks with this structure is the random-dot motion (**RDM**) discrimination task. The stimulus in this case is a cloud of flickering dots in which a fraction of the dots move in a given, fixed direction and the rest move in random directions. The subject watches the cloud for some time and must indicate the overall motion direction, typically either to the left or to the right, by making an eye movement to either a left or a right choice target. This particular type of stimulus is useful because the difficulty of the perceptual judgment can be tightly controlled by varying the coherence, i.e., the fraction of dots that move together. Also, there is a specific area in the brain that specializes in the analysis of visual motion, area MT, so a subject's behavior in this task depends crucially on how MT neurons respond; lesioning this area, for instance, greatly compromises a subject's capacity to perform motion discrimination tasks (Lauwers et al. 2000). In fact, in a series of elegant studies, Newsome and colleagues showed that there is an intimate, quantitative relationship between the behavior of a monkey in each trial of the RDM discrimination task and the neuronal activity evoked in area MT.

In their initial studies, Newsome and collaborators recorded from MT neurons, which respond selectively to motion in specific directions, in monkeys performing the RDM discrimination task (Newsome et al. 1989; Britten et al. 1996). They analyzed the responses of groups of neurons that preferred movement in one direction (say to the right) or the opposite (left), and made two important observations. First, as the dots moved to the right or to the left, one group of neurons was more active than the other, and the difference in activity varied as a function of coherence in a way that was similar to the monkey's own choice reports. More specifically, they compared the monkey's psychometric curve, which plots the probability of indicating motion to the right as a function of coherence, to an equivalent curve based on neuronal responses called the

“neurometric curve,” which is constructed by comparing the numbers of spikes evoked by a left- and a right-preferring neuron in single trials. Interestingly, the neurometric curves from pairs of neurons were very similar to the monkey’s psychometric curve, indicating that the animal’s sensitivity to motion could be fully explained by the sensitivity of the neurons.

The second observation they made referred to a small but statistically reliable correlation between the firing of the neurons and the monkey’s choices in individual trials, particularly when the motion was completely ambiguous (zero coherence). That is, when the RDM stimulus was uninformative, if a right-preferring neuron was slightly more active than average, the monkey was slightly more likely to indicate that the movement was to the right, and vice versa, when the neuron fired less vigorously than average, the monkey was less likely to make a decision in favor of the cell’s preferred direction. Although modest, the effect was reliable across neurons and stronger for units with higher sensitivities (Britten et al. 1996).

This result demonstrated a clear relationship between the behavior of single neurons and the behavior of a subject in single trials of a perceptual task. What is noteworthy here is not simply that a single neuron influences the monkey’s actions, which would be fairly trivial in the case of a motor neuron, for instance, the issue is that a single neuron contributes to what the monkey sees and thinks. The spikes fired by a neuron in a time window of a few hundred milliseconds have a measurable and predictable impact on the sensations that the monkey reports. Although this type of result is now relatively common, it is in fact quite remarkable, given the very large numbers of neurons in the brain that participate in any particular decision or judgment. Furthermore, it did not have to be this way. It is now known that the effects of single neurons on perceptual experiences are observable only because of the highly interconnected nature of the neural networks in the brain (Haefner et al. 2013); if the brain’s organization were different, such correlations between neuronal activity and perception would be undetectable.

Further Evidence of Competition Between Selective Pools of Neurons

Both lesion and single-unit studies provide correlative evidence that neurons may be involved in generating a particular behavior or that they convey sensory information that is crucial for such behavior, but they do not prove a direct, causal relationship. Electrical microstimulation can do so (Cohen and Newsome 2004). In microstimulation experiments, electrical current is delivered through an electrode, and its temporal pattern is such that the neurons within a certain radius of the electrode tip are activated. In this way, by stimulating during performance of a given task, it is possible to investigate what sensation those neurons transmit or, more generally, what effect their firing has on choice behavior.

This technique was exploited very effectively by Newsome and colleagues to provide further evidence that the activity of MT neurons directly contributes to the sensations of visual motion reported by monkeys. First, microstimulation of MT during performance of the RDM discrimination task resulted in an increased propensity of the monkeys to make a choice in line with the neurons’ preferred movement direction (Salzman et al. 1992). When neurons selective for leftward motion were stimulated, the monkey was more likely to choose the leftward target. Second, the bias produced by microstimulation was specifically in the preferred direction of the activated neurons regardless of the direction of the dots. This was established in a variant of the RDM task in which the dots were allowed to move in any direction and the monkeys were trained to indicate the perceived direction by making eye movements from the center of a circle to its edge, thus covering any angle within 360° (Nichols and Newsome 2002). Third, microstimulation was effective only when it overlapped in time with the RDM display, indicating that the firing of MT neurons is taken into consideration only during a certain critical time period within the sequence of events that comprise a choice trial (Seidemann et al. 1998). And finally, during stimulation trials, choices made toward the neurons’ preferred direction were sped up, whereas choices

made in the opposite direction were slowed down; but notably, the observed differences in RT were exactly as if the coherence of the dots had increased in the preferred direction of the neurons – unlike the somewhat less specific effects observed during stimulation in an oculomotor planning area (Hanks et al. 2006). So, when stimulating in MT, the measured choice and RT biases were coupled precisely as if the coherence of the RDM stimulus had been slightly different.

All of the results discussed so far based on the RDM discrimination task are in agreement with the first principle mentioned above, namely, that a perceptual discrimination results from a competition between neurons that are selective for sensory features that distinguish the available options. Numerous studies based on widely different experimental conditions indicate that this is, indeed, a general property of decision-making circuits. For instance, Afraz et al. (2006) trained monkeys to categorize images as either faces or non-faces. The animals reported their judgments by making an eye movement in one direction when a face was shown and in the opposite direction when a non-face (i.e., a random object) was shown. The difficulty of the task was varied by adding different amounts of noise to the images, such that classifying highly corrupted pictures was hard but doing so for relatively clear pictures was easy. Then, in some trials of the task, microstimulation current was injected into inferior temporal cortex, an area that is crucial for visual object recognition and is considered the end stage of the ventral visual processing pathway (Gross 1994). Again, as in the case of microstimulation of MT, the stimulation current generated a bias in the monkey's choices that was fully consistent with the sensory preference of the activated neurons: when the stimulating electrode was placed near a population of neurons that fired most strongly to faces, the monkeys were more likely to report that a face was shown. Significantly stronger effects were obtained when stimulation was applied in a particular time window (50–100 ms after image onset) rather than earlier or later, when the selectivity of the stimulated neurons was high rather than low, and when a large rather than a small number of face-

selective neurons were found around the electrode (Afraz et al. 2006). Thus, the specificity of the observed behavioral biases was highly consistent with the presumed properties of the artificially evoked activity. This experiment can be considered a generalization of the microstimulation experiments in MT (Salzman et al. 1992; Nichols and Newsome 2002) to a higher-order visual area and a much more complex class of visual stimuli, but mechanistically the conclusions are virtually identical.

Using a similar categorization task, Heekeren et al. (2004) used **fMRI** (functional magnetic resonance imaging) to investigate whether similar competitive mechanisms exist in humans. In each trial of their study, a noisy or degraded picture was shown and the subject had to categorize it as either a face or a house, and the difficulty of the categorization varied according to the amount of noise used. Faces and houses were chosen because these stimuli activate specific patches in ventral temporal cortex (analogous to inferior temporal cortex in monkeys) that are identifiable via fMRI, and their activations could be simultaneously resolved and monitored during the imaging sessions. The authors showed that the fMRI signal increased in the face-selective patches when the subjects reported seeing a face and decreased when they reported seeing a house, and conversely for the house-selective regions. Also, the strength of the responses decreased as the ambiguity of the displayed images increased. Thus, the results were consistent with the idea that the subjective experience of perceiving a face or a house depends on the relative levels of activation of face- and house-selective neurons within ventral temporal cortex, in agreement with the findings of Afraz et al. (2006).

A most striking demonstration of perceptual competition may be achieved under special sensory conditions based on ambiguous images. In that case, the conflict between two possible percepts is endless and unresolvable, and the moment-by-moment report of the subject's experience covaries across time almost perfectly with the activity of high-level visual neurons (Sheinberg and Logothetis 1997; Blake and Logothetis 2002). In binocular rivalry

experiments, different images are shown simultaneously to the two eyes – these can be simple, such as a vertical versus a horizontal grating, or complex, such as a house versus a butterfly – but only one of them is seen by the subject at any given time. The perceived image fluctuates spontaneously on a time scale of seconds, so if the image on the left eye is seen clearly, after a second or so, it is the image on the right eye that is seen exclusively. The transitions are stochastic, with the distribution of dominance times close to a gamma distribution. Presenting different images to the two eyes is convenient and efficient but not essential; similar effects can be obtained with normal (binocular) images that are ambiguous or illusory, such as the Necker cube.

What is remarkable in this paradigm is the close correspondence between the responses of neurons in high-level visual areas, such as inferior temporal cortex, and the subject's reports: if the images to the two eyes are, say, a face and a flower and the activity of a face-selective neuron is recorded, then whenever the neuron fires intensely the subject reports seeing a face, and vice versa, when the subject indicates seeing a flower, the neuron is relatively quiet, all this without the sensory stimuli ever changing (Sheinberg and Logothetis 1997; Blake and Logothetis 2002). Furthermore, during transitions, a change in neural activity (from low to high firing rate or vice versa) typically precedes a change in the subject's report (from the cell's non-preferred to the preferred image or vice versa). This indicates that populations of neurons that are selective for the left and right images alternate in their dominance to determine what the subject actually sees. The population responses reflect not only the stimuli but also an internal consensus that corresponds to the subjective perceptual interpretation of those stimuli. Importantly, this phenomenon is either absent or much weaker in earlier visual areas, such as primary visual cortex, where neurons predominantly encode the sensory stimuli regardless of the subject's awareness of them. Although the binocular rivalry paradigm requires very particular stimuli and presents a peculiar type of choice, because there is no correct or incorrect response, it reveals most eloquently the competitive nature of

the neural interactions that determine perceptual decisions. It is also interesting because the competition in this case seems to be purely perceptual, in that it is difficult to conceive in terms of a motor conflict between two possible actions, as has been done in many choice tasks and associated models (see below).

Deciding Is to Compare One Alternative Versus Another

The main question posed by Heekeren et al. (2004) in their categorization study mentioned above was this: if the subject's choice in each trial depends on the relative strength of the neural responses favoring faces versus houses, then where is such a comparison performed? Is it isolated to one area in the brain or distributed across a network? To answer this, the authors searched for brain locations for which the local fMRI signal was correlated with the absolute *difference* between the signals of the previously identified face- and house-selective regions. The rationale for this is simple: if two pools of sensory neurons provide perceptual evidence in favor of the two available options, then their responses must be compared somehow in order to generate an informed decision. Heekeren et al. (2004) found only one area that correlated closely with the difference in the face- and house-selective signals, the dorsolateral prefrontal cortex, and importantly, the activity in this area was predictive of the subject's choices across trials.

This study provides a particularly simple illustration (at least in appearance) of the comparison problem, but this is a key issue, because comparing separate sources of sensory evidence associated with alternative choices is the computation that lies at the heart of every discrimination. Many experimental and modeling studies in perceptual decision making have investigated this process, and two things have become clear: one, that the comparison arises gradually, both in time and across neural circuits, and two, that at least in species other than human, the comparison is intimately linked to the motor planning processes associated with the available (motor)

choices – and perhaps for some decisions they are indistinguishable (Cisek and Kalaska 2010). These findings essentially constitute the second computational principle stated earlier.

In the case of the RDM discrimination task, area MT provides the sensory evidence on which the perceptual judgment is based, but does not represent the decision itself. However, because this task typically requires subjects to indicate the net direction of motion with a saccade to one of two stationary targets, the corresponding motor plan to move the eyes should be indicative of the decision-making process (the alternative is that the saccadic plan simply represents the outcome of the decision process as computed in a different area, neither MT nor saccade related). Hence, investigators have recorded in areas of the brain responsible for planning eye movements, including the frontal eye field (FEF), lateral intraparietal area (LIP), and superior colliculus (SC), where microstimulation elicits saccades with precisely defined movement vectors. The idea is to understand how perceptual information (conveyed by the responses in MT) influences the oculomotor activity associated with a saccade (which conveys the monkey's decision). Note that the same rationale applies to any decision-making task in which the subject's judgment is reported via an eye movement or any other movement. In this approach, decision making is thus treated essentially as a problem of movement selection (Gold and Shadlen 2007; Cisek and Kalaska 2010).

Indeed, during the RDM task, the sensory information associated with the motion of the dots clearly modulates the oculomotor activity preceding a choice. To appreciate the specific effects that have been observed, first consider how oculomotor neurons fire before a saccade in a simple situation, when there is only one target in the visual field. When location x becomes the target of a saccade, the activity of neurons with movement fields at x starts increasing above the baseline level at a relatively constant rate (the buildup rate), and once the overall activity of that population exceeds a particular threshold level, then the saccade to location x becomes certain, with the onset of the eye movement

occurring about 10–20 ms after threshold crossing (Hanes and Schall 1996; Lo and Wang 2006; Heitz and Schall 2012). This buildup in activity from baseline to threshold is precisely what is referred to as a “motor plan.” Importantly, during saccades to single, unambiguous visual targets, which in monkeys typically take 100–300 ms, the buildup rate of the motor plan is inversely related to the measured saccadic RT: when the neural activity rises quickly (high buildup rate), the corresponding RT is short, and vice versa, when the neural activity rises more gradually (low buildup rate), the corresponding RT is long (Hanes and Schall 1996; Heitz and Schall 2012). From a modeling point of view, assuming that the rise in activity is linear (i.e., that the buildup rate is constant) is often a convenient simplification (Carpenter and Williams 1995; Brown and Heathcote 2007; Stanford et al. 2010).

Now, during the RDM task, two motor plans representing alternative choices compete with each other, and their buildup rates depend on the moving dots. When the coherence is high and the decision is easy, the buildup rate of one motor plan (the one congruent with the true motion direction) is much higher than the buildup rate of the alternative plan (which is congruent with the opposite direction as that of the dots); thus, the threshold for triggering a saccade is reached soon, the RT is typically short, and the choice is typically correct. In contrast, when the coherence is low and the decision is difficult, the two motor plans ramp up at similar, intermediate rates, and it takes longer for the motor conflict to be resolved; thus, threshold is reached late, the RT is typically long, and the probability that the choice is correct is close to chance. This interaction between motion information and oculomotor report via the buildup rates of the saccadic plans is very similar in LIP, FEF, and SC; is observed whether or not the monkeys have to wait for a go cue before responding; and varies only very subtly when four instead of two possible directions of motion are used (Shadlen and Newsome 2001; Horwitz and Newsome 2001a, b; Roitman and Shadlen 2002; Churchland et al. 2008). Thus, the oculomotor activity associated with the perceptual decision is neither purely sensory nor purely motor.

This scenario, in which the decision about the moving dots is instantiated as a competition between motor alternatives that is influenced by sensory information, has been successfully modeled by Wang and colleagues using relatively realistic networks of spiking neurons, which reproduce many features of the behavioral and single-unit experimental data in the RDM task (Wang 2002; Furman and Wang 2008). Simpler models, in which a decision variable rises to a threshold via a biased random walk, are surprisingly effective in replicating in quantitative detail much of the psychophysical data in this and other two-alternative forced-choice tasks (Smith and Ratcliff 2004; Palmer et al. 2005; Kraglich and Rangel 2011). Such reduced models, however, tend to be more difficult to interpret directly in terms of neuronal activity (Brunton et al. 2013; Zariwala et al. 2013; see below).

Gradual Influence of Perception on Motor Planning: Open Gate Versus Closed Gate

Gold and Shadlen (2000, 2003) used an elegantly designed microstimulation experiment to measure how perceptual information modulates the evolving decision-making process in FEF at each point in time. While monkeys performed the RDM discrimination task, some trials were interrupted by applying electrical microstimulation at a (suprathreshold) level sufficient to trigger a short-latency saccade. By analyzing the elicited saccade vectors in relation to the directions of the two possible choice targets, the authors determined which option was being favored at the moment the saccade was triggered; in this way, they could read out the state of the oculomotor competition before it was naturally resolved. By turning on the stimulator at different times relative to the onset of the motion stimulus, they could establish which motor plan was winning at any given time, and by how much. The patterns of evoked eye movements that they obtained indicated that the perceptual decision evolves gradually and that it depends on both viewing duration and motion strength: larger deviations in favor of

the correct motor choice were obtained as the coherence increased and as the monkey had more time to view the RDM stimulus. There was no temporal discontinuity or sharp transition in the data, as would have been expected if the saccadic plan reflected the presence or absence of a fully formed perceptual decision generated elsewhere. Therefore, in this case, the development of the perceptual judgment was indistinguishable from the development of the motor plan for indicating that judgment.

This result is conceptually quite important because it suggests that making a perceptual decision could be the same thing as making a motor choice; they could be one and the same neural process, as instantiated by various computational models in which decisions arise within motor planning circuits (Wang 2002; Cisek 2006; Beck et al. 2008; Furman and Wang 2008; Cisek et al. 2009; Stanford et al. 2010). This idea is attractive because it matches experimental data from many tasks, but it cannot be the whole story because, clearly, there are many perceptual decisions that do not lead to any immediate, predictable actions. Indeed, Gold and Shadlen (2003) performed a variant of their microstimulation experiment in which the direction of motion of the dots, left or right, was reported by making a saccade to a red or a green target, respectively. These targets, however, appeared after the RDM stimulus and at locations that varied randomly across trials, so the correct eye movement could not be predicted based on the motion of the dots alone. In that case, according to the observed saccade deviations, the motion stimulus had essentially no effect on the activity of FEF during the stimulus presentation period. Therefore, the ongoing influence of perceptual information on motor planning was seen only when there was a predictable association between the perceptual options (dots moving left or right) and the motor options (saccade to the left or to the right).

One way to think about these results is this: when there is a predictable mapping between perceptual and motor alternatives, perceptual information flows in an “open-gate” mode in which it continuously influences the competition between (pre-identified) motor plans; in contrast, when the

mapping is unknown, the gate is closed, and the perceptual decision is constructed and stored elsewhere (Cisek 2012). Presumably, the closed-gate mode is necessary for making decisions that will turn into actions over a long term or that are associated with as yet unspecified actions, whereas the open-gate mode may be necessary for making rapid decisions for which any delay in execution would be detrimental; think of stopping a penalty kick, hitting a fastball, or returning a 130 mph serve. In this latter mode, the system might bypass all processes that are not essential, thus explaining the apparent simplicity of the decision-making circuitry (e.g., Wang 2002; Furman and Wang 2008).

In this respect, it is interesting to compare the results of Gold and Shadlen (2000, 2003) to two sets of studies in which similar open-gate mechanisms seem to operate at widely different time scales. In the work of Stanford and colleagues (2010; Shankar et al. 2011), monkeys perform a choice task that simulates an urgent decision. The rules are simple: two yellow spots are shown and the subject must look at one of them when instructed. Crucially though, the cue that specifies which choice is correct (one spot turns red and the other green) is revealed *after* the go instruction, so the two motor plans always start *before* any perceptual analysis. The cue is delayed unpredictably and may not be shown at all in any given trial. In this way, depending on how much time the subject has to view the cue, choices go from fully random (i.e., guesses) to fully informed – but they are always relatively fast (RT is ~250 ms). Using this technique, Stanford and colleagues (2010; Shankar et al. 2011) found that, behaviorally, subjects required a total of about 130 ms of cue viewing time to reliably discriminate the red and green stimuli, but there was a much shorter, critical time window during which performance went from chance (< ~100 ms of viewing time) to 75% correct (at ~130 ms of viewing time). Now, neurophysiologically, the responses of oculomotor neurons recorded from FEF during performance of the task also changed as functions of cue viewing time: the buildup rates of the target- and distracter-related motor plans increased and decreased, respectively, once the cue information

became available, and the time course of the modulation matched that of the behavior. Thus, the results are consistent with the open-gate mode in the experiments of Gold and Shadlen (2000, 2003), except that the perceptual decision – or equivalently, the motor choice – evolved over a much shorter time scale (~30 ms).

Cisek and colleagues also concluded that a fundamental characteristic of decision-making processes is to resolve conflict between actions that may be planned simultaneously (Cisek and Kalaska 2005, 2010; Cisek 2006), but this was based on studies involving arm movements and a much slower time scale for responding (~500 ms). In one of their tasks, a sensory cue was shown first, followed by two choice targets of different colors, and the monkey simply had to reach for the target matching the color of the cue. In this case, the activity recorded from premotor cortex was associated almost exclusively with the correct target and showed little evidence of a conflict. In contrast, in a second task, the association rules and required movements were the same but the order of events was reversed: the two choice targets appeared first and the sensory cue that differentiated target from distracter was shown later. Notably, in this case, both motor plans were strongly activated initially, and the arrival of perceptual information resolved the conflict in favor of the correct one (Cisek and Kalaska 2005). In their view, decision making does not follow an intrinsic sequential arrangement of perception → cognition → motor selection; rather, perceptual information and other task contingencies, such as reward value or motivation, bias a motor selection process that is activated whenever multiple actions are possible (Cisek and Kalaska 2010). Motor preparation is informed by relevant cognitive or perceptual events whenever they occur but does not wait for them to unfold. The internal conflict gets resolved with them (leading to informed choices) or without them (leading to guesses). Klaes et al. (2011) reached similar conclusions too. Evidence of a continuous influence of perceptual input on motor representations (i.e., an open gate) is seen even when decisions require very high-level cognitive processes, such as language (Spivey et al. 2005).

Neurons that are considered decision related typically have both sensory properties (associated with specific sensory features) and motor properties (associated with a specific choice), and their rising activity typically represents a motor plan with a buildup rate that depends on the available perceptual information. However, if this is a truly general mechanism, then the gradual rise to a threshold could be a prominent signature of decision-making processes in general, regardless of the specifics of the sensory input and the subsequent motor activity. O'Connell et al. (2013) searched for such a signature in the EEG of human subjects. This was challenging because although the EEG has excellent temporal resolution (~1 ms), its spatial resolution is extremely poor. However, they used an elegant task design that allowed them to overcome the usual technical limitations and identify a neurophysiological signal with all the properties expected from an evolving decision variable. Participants viewed a striped annulus that was constantly flickering and whose contrast varied slowly (over ~2 s) during certain, unpredictable epochs, and their task was to press a button when they were sure that the stimulus was fading. The flicker was useful for identifying signals specifically related to the stimulus, and the slow time scales guaranteed that contrast decreases were detected accurately but with highly variable latencies. So, three signals were identified in the EEG, a standard one associated with motor activity, a sensory-related one that tracked the flicker, and a third one termed the central parietal positivity, or **CPP**. The CPP corresponded to an evolving perceptual decision in several ways (O'Connell et al. 2013): (1) it rose gradually, and before each button press, it reached a constant level that was independent of RT; (2) its rate of rise strongly correlated with RT; (3) when task difficulty was varied by making the contrast changes more or less slow, the CPP amplitude predicted the subject's choices, i.e., hits, misses, or false alarms; (4) it was identical for increases versus decreases in contrast and for two versions of the task based on visual and auditory stimuli, so it was modality independent; (5) it was absent when attention was directed away from the annulus and the subjects

had to detect an unambiguous, essentially instantaneous change in the fixation point; and (6) it was present – although significantly attenuated – in the absence of overt action. These results agree with the idea that ramping signals with mixed sensory and motor features are the hallmark of perceptual decision making, even when the associated action is nonspatial and relatively subtle (a button press).

In contrast to the studies just discussed, much less is known about perceptual decision making in tasks that impose a closed gate. In such cases, for instance, when the sensory-motor mapping is unpredictable, there may be some residual activity in motor planning areas, but characterizing it has been challenging (Horwitz et al. 2004; Bennur and Gold 2011). Also, what happens when the current sensory signal informs an action that may occur at an unknown time in the future, with other actions performed in the intervening time? Do such decisions also involve a progressive accumulation process with an activity threshold that serves as a trigger? Remarkably, recent work (Hayden et al. 2011; Krajbich and Rangel 2011) suggests that this may indeed be the case.

Hayden et al. (2011) developed an oculomotor choice task that mimics foraging behavior. In each trial, the monkey could choose between staying in the current “foraging patch” (i.e., making a saccade to a small square) and switching to a new patch (i.e., making a saccade to a bar). The first reward obtained in a new patch was always large, and subsequent rewards decreased steadily with each consecutive stay, but crucially, switching to the new, high-reward patch carried an up-front cost in the form of a long time delay (the “traveling time”), which was explicitly indicated by a visual cue (the length of the bar). Thus, for each choice, the monkey had to weigh the high cost of a large reward against the low cost of a diminishing reward. Because the traveling time varied for each new patch, monkeys exhibited a wide range of switching times, but their overall behavior was close to optimal in that the total reward harvested per session was close to the theoretical maximum. Notably, some neurons in the dorsal anterior cingulate cortex (**dACC**), an area that is generally linked to behavioral adjustment and the valuation of actions (Kennerley and Walton 2011),

indicated the likelihood of making a switch. These dACC neurons responded only around the time of the saccadic choice in each trial and were otherwise quiet. The perisaccadic response was weakest following a switch, but with each subsequent stay, it increased in intensity, and when it reached a particular level, the monkey again switched to a new patch. This increasing dACC activity is clearly analogous to the rise to threshold typical of motor plans, but it differed in various ways: it was intermittent rather than sustained, lacked any spatial selectivity, and developed over many intervening choices spanning tens of seconds. Nevertheless, it was associated with a particular action and was sensitive to reward size, and both its buildup rate and threshold level depended on the switching cost, as given by the visual cue. So, although a causal link still remains to be demonstrated, in this task the decision to switch patches again correlates with neural activity that rises to a threshold and is modulated by perceptual information, even though the temporal constraints and internal computations imposed by the task are much different from those reviewed earlier.

Further exploration of decisions made in the closed-gate mode, which are intrinsically more abstract, is an important goal for future studies (Padoa-Schioppa 2011; Cisek 2012).

Perceptual Decision Making Based on Tactile Stimuli

Beyond vision, similar perceptual discrimination mechanisms have been identified by Romo and colleagues in the somatosensory system of monkeys (Romo and Salinas 2001, 2003). Although the computational principles discussed above remain valid in this case, there are also some notable differences with respect to the studies based on RDM and other visual stimuli.

In the vibrotactile discrimination task used by Romo and colleagues, two mechanical vibrations of frequencies f_1 and f_2 in the flutter range (5–40 Hz) are delivered sequentially by a small, oscillating probe similar to the tip of a ballpoint pen, and the monkey has to press one of two push buttons to indicate whether $f_1 > f_2$ (medial button)

or $f_2 > f_1$ (lateral button). Note that the relevant comparison in this case is between the activities of the same group of neurons but sampled at different times; the circuit must compare the responses to the second stimulus to a stored memory trace of the responses to the first stimulus. In this paradigm, task difficulty is controlled by varying the difference between the two frequencies, but to a certain extent, it also depends on the delay between the two stimuli (Hernández et al. 1997). Neurophysiological recordings have shown that, again, two groups of sensory neurons are crucial for task performance: for one group, the firing rate increases monotonically as a function of stimulus frequency, so those neurons fire most intensely to frequencies near 40 Hz, whereas for the other group, the firing rate decreases monotonically with stimulus frequency, so their most vigorous responses are to frequencies near 5 Hz. Although such neural code for vibration frequency is simple, the neural operations required for discriminating f_1 versus f_2 are somewhat more complicated than in the RDM case, because both neuron types are activated twice (for the first and second stimuli) and the responses to the first stimulus must be stored in short-term memory.

Now, there are four interesting results about the neural underpinnings of this perceptual decision-making task. First, the preference for high frequencies develops earlier than that for low frequencies; that is, in primary somatosensory cortex (S1), there is a relatively large fraction of neurons with firing rates that increase as functions of stimulus frequency, whereas neurons with the opposite selectivity are virtually nonexistent (Salinas et al. 2000). In contrast, in secondary somatosensory cortex (S2) and areas downstream, the two types of selectivity are approximately equally common, roughly 60% monotonically increasing versus 40% decreasing (Salinas et al. 2000; Romo and Salinas 2003). This suggests that the circuit actively develops a sensory representation that naturally lends itself to a competition between two neural populations with opposite feature preferences.

Second, the activity of neurons in both S1 and S2 is significantly correlated with the monkey's choices in single trials (Salinas et al. 2000); that is,

when a neuron fires more intensely than average on a particular trial, the monkey is more likely to make one choice than the other on that trial (which choice depends on the tuning of the neuron, i.e., whether it is monotonically increasing or decreasing with stimulus frequency). Consistent with a causal role in generating the subject's perception of vibration on the skin, the direct activation of S1 neurons via microstimulation triggers perceptual sensations that, as far as can be measured psychophysically, are indistinguishable from those evoked by natural, mechanical stimuli (Romo et al. 1998). In particular, when the electrical current is of high frequency and the stimulated neurons presumably fire more intensely, the monkeys report high-frequency sensations, and vice versa when the stimulated neurons presumably fire weakly, the monkey reports are consistent with low-frequency sensations. This makes sense given the neural code for stimulus frequency found in S1, where the higher the stimulus frequency, the higher the evoked firing rates of those S1 neurons that respond to flutter stimuli. Furthermore, the microstimulation results remain true even when no mechanical stimuli are applied at all and the monkey's judgments are based on two artificially evoked sensations (Romo et al. 2000), which demonstrates that all the perceptual information needed to perform the task is derived from the firing of a localized population of neurons with a particular type of stimulus selectivity.

Third, neurons from multiple cortical regions (S2 and downstream) continue to fire throughout the delay period between the presentation of the first and second flutter stimuli, but these sustained responses are most robust in the prefrontal cortex (Romo et al. 1999; Romo and Salinas 2003), the area that is most strongly linked with short-term memory performance (Miller and Cohen 2001). The responses of PFC neurons are thus the neural correlates of the remembered first stimulus during the task.

And fourth, many neurons downstream from S1 that are activated during the comparison period of the task reflect the monkey's decision (Romo et al. 2002; Romo and Salinas 2003; Hernández et al. 2010). That is, shortly after the second

stimulus starts, some neurons fire very strongly whenever $f_1 > f_2$ but almost not at all whenever $f_1 < f_2$, and a complementary population responds in the opposite way, firing most strongly whenever $f_1 < f_2$. What is quite remarkable is that these same neurons typically respond to the first and/or second stimuli in a standard sensory fashion, that is, with firing rates that increase or decrease monotonically with f_1 or f_2 . Thus, in S1, the evoked responses are, in essence, fully determined by the current sensory input and are rather insensitive to task contingencies. In contrast, in S2 and downstream premotor areas, neurons also respond to the stimuli, but in general, their selectivities change dynamically: the responses first reflect f_1 or f_2 but later change to reflect either the difference between f_1 and f_2 or the sign of the difference, which is ultimately the variable that matters for the monkey's behavior. These interactions can still be understood as competitions between pools of neurons with different selectivities, except that for most neurons the pool membership changes dynamically as the relevant sensory information becomes available. Again, this is in line with the idea of an open gate through which sensory information flows and guides motor preparation, except that here the responses in premotor areas first reflect the sensory stimuli and then develop into a well-defined motor plan that correlates with the subject's motor choice.

Several models have been proposed to explain the neuronal dynamics observed in this task, and although those models capture many important features of the data, such as the sustained working-memory responses that encode f_1 and the comparison signals that encode the sign of $f_2 - f_1$, one aspect of the recorded data for which a plausible account is still lacking is the wide repertoire of response selectivities found experimentally (Jun et al. 2010; Barak et al. 2013). Neuronal preferences to various combinations of f_1 and f_2 vary tremendously, both across neurons and over time within the same neurons, but why? Answering this question may be key for obtaining a deeper understanding of the circuit mechanisms at play during perceptual decision making (Barak et al. 2013).

Integration of Sensory Evidence and the Speed of Perceptual Decisions

Studies based on the RDM discrimination task and others suggest that perceptual information can accumulate slowly over time to increase performance. Conceptually, the idea is that although instantaneous sensory responses are inevitably noisy, the random fluctuations in this activity can be averaged out by combining samples over time. This results in a more informative, integrated sensory response that gradually ramps up toward a discriminability criterion (Gold and Shadlen 2007; Beck et al. 2008). Simple integrator (or drift-diffusion) models that instantiate this process (Smith and Ratcliff 2004; Palmer et al. 2005) thus account for three general observations: (1) that RTs increase with increasing difficulty, (2) that performance increases with stimulus duration, and (3) that subjects can internally trade speed for accuracy (Zariwala et al. 2013). A key question is whether this is an essential mechanism – or perhaps *the* essential mechanism – for generating perceptually guided decisions. The issue is about how the second computational principle discussed above should be interpreted: does the rising activity associated with decision making represent primarily integrated sensory information, regardless of any movement preparation?

In our view, this sensory or computational interpretation is one extreme within a range of possibilities. Undeniably, sensory stimuli may influence motor plans even when the corresponding actions are highly stereotyped and predictable and the sensory information is irrelevant (Dorris et al. 2007). However, motor plans with a wide range of buildup rates arise even when the sensory signals triggering them are highly unambiguous (e.g., a single, high-contrast stimulus) or when no stimulus is present (e.g., spontaneous eye movements in the dark). This happens in the very same areas, and indeed the very same neurons, that are supposed to integrate sensory evidence. Furthermore, experimental evidence for a threshold mechanism is substantial only for responses linked to specific, imminent motor actions, saccades in particular (Hanes and Schall 1996; Roitman and Shadlen 2002; Stanford et al.

2010; Hayden et al. 2011; Heitz and Schall 2012), and perceptual difficulty and RT may be decoupled (Stanford et al. 2010; Salinas and Stanford 2013; Zariwala et al. 2013). So, a conservative answer to the question posed above is “not necessarily.” Here, we have adopted the view that, under many circumstances, namely, “open-gate” tasks, decision-related responses are motor plans with buildup rates that are modulated by perceptual information. That way, the yes/no question above turns into one of degree: how strongly does the buildup rate of the rising, choice-related activity depend on perceptual information?

This point merits some additional discussion for two reasons: first, because it involves key problems in computational neuroscience, such as the role of neuronal variability in determining behavior and the efficiency of neuronal population codes (Wang 2002; Beck et al. 2008), and second, because while integrator models have been highly successful at replicating psychophysical data in a vast variety of tasks (Smith and Ratcliff 2004; Palmer et al. 2005; Kragbich and Rangel 2011) and are thus the default tool for modeling decision-making performance, there are alternatives (Carpenter and Williams 1995; Brown and Heathcote 2007; Shankar et al. 2011). Two studies place important constraints on the possible underlying mechanisms for integrating sensory evidence.

Brunton et al. (2013) designed an auditory discrimination task in which two series of clicks stream concurrently from two loudspeakers, one on the left and one on the right, and the subject must indicate which side produced more clicks after a given amount of time (100–1200 ms in rats). The difficulty of the task depends on the difference in the number of clicks from the two sides, but the timing of individual clicks is random (it follows Poisson statistics), and the total click rate is always the same and relatively high (40 clicks/s), so the subjects cannot simply count. Now, any computational scheme for solving this task must integrate the clicks from the two sides and compare the results, but because each click is a discrete event, within any conceivable model, it is possible to determine how each

individual click contributes to the decision in each trial. This is a unique and tremendously powerful aspect of the task, for suppose that a model A with n parameters is constructed. The parameters can be fit using, say, half of the data, and then the model can be tested on the other half, but here is the key: once model A is specified, it will make a prediction about the expected outcome, left or right choice, *in each test trial*, because each trial consists of a unique sequence of clicks. Thus, model and behavior can be compared without averaging across trials. For this reason, many models with many parameters can be tested and differentiated unambiguously; the numbers of degrees of freedom they require (n) are always tiny compared to the dimensionality of the data that constrain them. Brunton et al. (2013) contemplated large families of integrator models that differed in their dynamics, time constants, sources of noise, etc., and compared their performance to that of individual rat and human subjects. They found that, for most subjects, there was no noise in the accumulator, and performance was limited by sensory or encoding noise. That is, a click could be missed or could be assigned to the wrong speaker, but once it was accounted for, its effect never faded. So, clicks that occurred near the beginning or the end of the trial had equal influence; the accumulator memory itself was perfect. In a standard integrator or drift-diffusion model, by contrast, the accumulator noise would have been high. This result is quite counterintuitive. It suggests that although the integration process itself can indeed be extremely efficient over a time scale of seconds, its mechanism is very different from the biased random walk assumed by standard models, at least under the conditions of this task.

Finally, when exposure to a sensory stimulus is prolonged, how much can performance increase? The answer to this question may depend heavily on task and stimulation conditions and on how these relate to an animal's natural behavior, but is there a general pattern (Uchida et al. 2006)? In the RDM discrimination task, behavioral studies in humans suggest that when coherence is relatively low, performance increases with the duration of the motion stimulus up to ~ 2 – 3 s of viewing time

(Burr and Santoro 2001; Palmer et al. 2005). But there may be something special about manipulating coherence to produce a weak motion signal: such long integration time constant is seen when coherence is low (and contrast is high) but not when the contrast of the dots is low (and coherence is high), in which case integration times are an order of magnitude lower (Burr and Santoro 2001). Also, a detailed analysis of neural activity in the standard RDM task suggests that the effective integration time in monkeys is more likely to be ~ 400 ms (Kiani et al. 2008). These results are consistent with the analysis of Uchida et al. (2006), who argue that for the most common perceptual judgments, such as those typically associated with saccades or sniffs, performance stops increasing beyond a fairly short period of sensory evaluation of ~ 200 – 300 ms. So, most perceptual decisions are fast. Long integration times may occur for relatively abstract or highly cognitive tasks – and relatively specialized circuit mechanisms are likely required to integrate robustly over a period of seconds or more, given the much shorter time constants of neurons and synapses. However, the more common scenario is likely to be one in which sensory information is sampled and processed quickly during short, discrete events, and there is little or no benefit in extending the deliberation period in such cases (Uchida et al. 2006).

This conjecture was directly examined by Zariwala et al. (2013), who investigated how the accuracy of perceptual choices changes with deliberation time in rats performing an odor categorization task. In each trial, a mixture of two odors was delivered, and the rat had to indicate which odor was present in a higher proportion. Under standard experimental conditions, the rats responded at any time after stimulus onset, and their performance varied between near chance (50% correct, for mixtures near 1:1) and near perfect (100% correct, for mixtures near 1:0 or 0:1) without a significant variation in odor sampling time, which was about 250 ms (here, the RT was equal to the sum of the odor sampling time plus the rat's movement time). So, in contrast to what is generally seen in, say, the RDM discrimination task (Roitman and Shadlen 2002; Palmer

et al. 2005), in this case, large variations in performance were not accompanied by changes in stimulus evaluation time. The authors attempted to reveal or create such a dependence through a large battery of task variants in which reward, punishment, trial length, response time, and stimulus and response predictability were manipulated, creating ample opportunity and motivation for the animals to integrate sensory information over long times. In every case, large changes in accuracy or response speed were achieved, yet no evidence of a trade-off was ever seen. When the rats extended their odor sampling time, performance did not increase, and vice versa, when performance did increase, there was no change in their timing relative to that in the standard task. Apparently, sampling the stimulus beyond 200–300 ms had no benefit (Zariwala et al. 2013).
